MANAGING AGRICULTURAL DEVELOPMENT IN AFRICA

FOREWORD

The MADIA study and the papers comprising this MADIA Discussion Paper Series are important both for their content and the process of diagnosis and analysis that was used in the conduct of the study. The MADIA research project has been consultative, nonideological, and based on the collection and analysis of a substantial amount of concrete information on specific topics to draw policy lessons; it represents a unique blend of country-oriented analysis with a cross-country perspective. The conclusions of the studies emphasize the fundamental importance of a sound macroeconomic environment for ensuring the broad-based development of agriculture, and at the same time stress the need for achieving several difficult balances: among macroeconomic, sectoral, and location-specific factors that determine the growth of agricultural output; between the development of food and export crops; and between the immediate impact and long-run development of human and institutional capital. The papers also highlight the complementarity of and the need to maintain a balance between the private and public sectors; and further the need to recognize that both price and nonprice incentives are critical to achieving sustainable growth in output.

The findings of the MADIA study presented in the papers were discussed at a symposium of senior African and donor policymakers and analysts funded by USAID in June 1989 at Annapolis, Maryland. The participants recommended that donors and African governments should move expeditiously to implement many of the study's valuable lessons. The symposium also concluded that the process used in carrying out the MADIA study must continue if a stronger, more effective consensus among donors and governments is to be achieved on the ways to proceed in resuming broad-based growth in African agriculture. The World Bank is committed to assisting African countries in developing long-term strategies of agricultural development and in translating the MADIA findings into the Bank's operational programs.

Summary and Policy Recommendations

In this paper we explore the relationship among population densities, agricultural production, land, labor, and rural incomes to expand the explanatory base of the Boserup hypothesis, which holds that with increasing population densities, a corresponding shift to greater agricultural production and more intensive use of the land takes place autonomously through the development of market forces. The movement away from traditional area-extensive farming methods is associated in the model with higher levels of technology, labor, and capital investment in land. In view of the rapid rates of population growth in Africa and the decreasing frontier, the question arises: "how far can market forces alone induce a productivity-enhancing process of agricultural intensification in Sub-Saharan Africa, and to what extent must it be complemented by an active public policy to support broad-based agricultural development?" The answer is critical to the increasing concern about food security and environmental degradation prompted by rapid population growth on the one hand, and on the other, to the pressure on governments to privatize smallholder services because of fiscal problems and questions about the efficiency of the public sector. To address these issues, the paper surveys existing literature and compiles data at the regional level for the six MADIA countries to isolate variables in the equation linking the intensity of land use, the increasing opportunity costs of idle or fallow periods, the effects of continuous cropping on the soil, and their policy implications.

Two types of intensification are distinguished in the paper. The first type, identified by Boserup, occurs spontaneously as more land is cropped more frequently in response to higher population densities. The second depends more on policy and incentives for a shift to crops of higher value or higher yields, or to more productive land. The spontaneous movement toward better adapted technology and higher levels of productivity was observed first in the development of Europe and Asia, a process we have termed "autonomous intensification." This paradigm of demand-led growth has served as the standard model, but worsening conditions in Africa are casting doubt on its value as a historical precedent. A combination of apparently more fragile African soils, declining rainfall, and historically unprecedented population growth rates in circumstances of unequal political power between the mass of smallholders and the privileged few makes the exclusive dependence on the market for achieving rapid growth in productivity more questionable in Africa. The paper documents several inherent limitations in the original model, e.g., (i) the negative effects of extremely rapid population growth as compared to the slowly rising densities envisaged in the hypothesis; (ii) the substantial concentration of population, even in land-abundant countries; (iii) the conflict between social and private gain of large family size at low levels of labor productivity for poor households; (iv) the tendency to "mine" the land for immediate survival versus the social need to protect soils as a productive resource; and (v) unequal access to land and even expropriation from smallholders as land values increase. The limitations of the hypothesis have not been easy to document because of contradictory and inadequate information about such matters as the extent of arable land remaining, but the scattered evidence presented in the paper suggests that the environmental damage caused by deforestation, decline in soil fertility, and retrenchment into subsistence and wage labor may well outweigh the effects of autonomous intensification. The movement against autonomous intensification is associated with rapidly declining farm sizes for the majority and marketed surpluses coming from fewer sources.

The second, less obvious type of intensification must therefore extend the Boserup hypothesis to include measures of output and productivity as well as the frequency of cropping. The process of using an increased role of the state to enhance productivity we call "policy-led intensification." The paper shows that higher yields, better inputs, and larger incomes for small farmers do not axiomatically follow from higher population densities or more frequent cropping of the land. Three measures of this latter type of intensification are particularly salient. Research indicates that:

1. **Shifts to Areas of High Potential** (and subsequent expansions onto marginal areas) occur spontaneously, but are in some cases restricted either explicitly by public policy toward land use or by natural or social causes. In the MADIA sample, population naturally gravitates toward the most productive land (where returns per hectare are highest), except where disease and pests pose a significant health problem, or where land policy proscribes this type of shift by giving a few estates preferential access to land over small farmers (as in Malawi) or constrains population movement (as did the Ujamaa policy in Tanzania). In other cases (such as Kenya), smallholders have recourse to legal ownership, but the process of titlement is fraught with unequal access to capital and land, due to ethnic biases, conflicting tenure customs, and registration fees. In situations of high population densities, the paper documents a phenomenon of outward migration to marginal areas when land in high potential areas is no longer accessible. This type of "regressive intensification," which simply amounts to mining nutrients from the soil, is not sustainable but is becoming pervasive.

2. **Shifts to Higher-Yielding Crops** by a large number of small farmers are made urgent by population pressure but remain dependent on policy. One way of improving crop yields is to promote high-yielding varieties of seed and complementary modern inputs such as fertilizers. The extent to which research priorities are tailored to the needs of small farmers will critically affect whether the "improved" planting material will have local appeal. If new seeds require additional cash inputs, are vulnerable to drought, do not store, process, taste good, or in any

way increase the element of risk in cropping, they will probably not be adopted even where population density is high. Adopting hybrids or using more inputs to boost yields will depend on the degree of farmer confidence in the market to purchase crop surpluses. The case of hybrid maize in Malawi is one such example. Similarly, in Senegal the paper documents a return to planting sorghum and millet, reflecting the farmers' desire for greater food security over potential (but risky) gains from higher-yielding or higher value crops at international market prices.

3. **Shifts to Higher Value Crops** depend as above on farmer confidence in the market, but also on the legal right to grow such crops. Ironically, population density appears to have little bearing on whether governments encourage or circumscribe smallholder production of cash crops. (Nonfood crops mainly produced for export have in a traditional parlance been called cash crops and data for a number of countries is reported as distinguishing between cash and food crops although food crops are also frequently sold for cash.) Densities are extremely high in Malawi and low in Tanzania, but each has pursued policies effectively curbing the supply response of smallholders to export crops. Either they cannot grow high value crops, or they have until recently had no incentive to do so. At the other extreme are Kenya and Cameroon. Although densities run much higher in Kenya, both have adopted policies enabling the small farmer to reap the fruits of higher value crops. These policies include ensuring rural transport, passing along close to world prices, and providing a variety of support services that enable small farmers to grow these crops.

The paper demonstrates how over time the changing demography of a country will alter relative opportunity costs and factor endowments; these changes will be most visibly manifest in the first type of intensification. High on-land densities, however, do not lead directly to progress in intensification as defined in this paper. The shift to higher-yielding and higher value crops and more productive land, as opposed to merely cropping the land more intensively and "mining" soils, requires that changes in factor costs be reflected in agricultural pricing and marketing, land tenure, and crop research policy. Three countries in particular—Kenya, Malawi, and Cameroon—have provided a stable policy environment and performed well, but broad-based growth was achieved only in Kenya, and even there gains in the smallholder sector came mostly through shifts to higher value crops such as tea rather than improvements in yields per hectare, as was the case in the large farm sector. In circumstances where price distortions are not compensated for by public initiatives or policies do not facilitate the move to intensification, environmental degradation will increase as a very rational response to the conditions of rural households.

The paper finds that the most direct means of addressing the problems of rapid population growth and environmental stress include among others the following:

- **Redefining land policy:** The land base and the degree of population depending on it for their livelihood need to be assessed. When left to market mechanisms, access to land must be ensured by policy measures to overcome the various constraints (social, cultural, economic) to equal access. Land policy must be complemented by a detailed inventory of data on rights to land, its use, potentials, and availability. The paper documents that despite massive amounts of external aid to Africa for nearly a decade and a half, such most basic information is not widely available: it simply has not been a priority for either governments or donors. Such data facilitate public debate within each country on the sensitive land issue and obviate the tendency for it to become part of highly visible lending conditionality. Bilateral donors with lesser perceived power than multilateral agencies such as the World Bank need to take a lead in this crucial but basic task of helping African countries to develop and analyze information on land policy by encouraging African scholars to work on the issue, and by helping to implement an equitable legal framework.

- **Stabilizing production and consumption policies:** Production policy must aim toward rapid, equitable, and highly participatory growth. That process will require stable buying and selling prices to increase farmer confidence to grow high value crops and rely on the market to provide food staples. Predictable or reliable incentives and clearly stated national objectives will help farmers to plan ahead and finance investments in the land and sustain broad-based productivity increases. The following means are available to ensure that end:

  - **Targeting crop research:** introducing seed varieties that reduce risk and complement traditional farming strategies. Integrating soil management techniques, such as nitrogen-fixing fodder crops and leguminous trees that retain soil and moisture. In land-scarce countries, developing higher-yielding varieties, which may require complementary inputs, that meet consumer and producer preferences.

  - **Improving rural physical and social infrastructure:** especially in high potential areas, investments in roads, input and output marketing channels, schools, and health services will show high returns. They will also be vital in bringing new information in primary life expectancy and encouraging migration into lower density but potentially more productive areas.

  - **Accelerating fertilizer use:** introducing and maintaining affordable prices and physical access for smallholders to increase the productivity of scarce land in the short and medium term including the judicious use of subsidies when necessary. Although a more holistic and appropriate strategy will rely more on locally produced inputs, hybrid seed may have to be accompanied by other chemical inputs, such as herbicides, for adequate returns.

  - **Extending credit:** increasing the availability of rural capital to smallholders will facilitate the adoption of better tools, seeds, and other inputs. Institutional credit will be required until rural financial markets develop and rural savings can be mobilized.

  - **Granting access to export markets:** giving small farmers the right to grow high value crops and the means to market them.

- **Rethinking population policy:** In absence of the above, population policy by itself may be incapable of reigning in problems of food security. In addition to the above, governments must think about reevaluating a *laissez-faire* approach to population growth given the conflict between private household and social gains. Although traditionally considered land-surplus, weak agricultural performance and accelerating rates of population growth in Africa are making international donors and a growing number of African policymakers question the benefits of high population growth. But without pursuing policies that increase household labor productivity, which among other things includes use of modern inputs, and without investment in human capital (education, health, water) that increases labor productivity and life expectancy, this conflict between private and social gain will not be reduced and population growth will continue unabated.

Failure to address these crucial policy areas will lead to increasing stress on the environment. Neglect in one policy area will not remain isolated, but will because of interdependence between the environment, agriculture, and economic performance impact with negative repercussions in other sectors of the economy.

Introduction

The interaction between population growth, the environment, and agricultural intensification raises the most compelling and most controversial issues currently facing developing countries. Given low initial population densities, the benefits of increasing population on agricultural development have been widely documented (Boserup 1961, 1981; Ruthenberg 1982); these authors have argued that slowly increasing population densities have desirable effects on technical change, land and labor productivity, and rural per capita incomes through changes in relative factor prices. Others have pointed out that while high population densities may be desirable in stimulating rural markets and technological adaptation, rapid population growth is very costly to countries at early stages of development (World Bank 1984). This paper shows that the environmental damage from the reduction of bush fallow, the more intensive use of land without supplementary biological and chemical inputs, and the depletion of forestry resources complicates the transition from low to more densely populated areas as originally envisaged in the Boserup hypothesis.

Many of the benefits associated with high population densities are seen by Boserup, Ruthenberg, and more lately Binswanger et al. (1986) as being derived mainly through market forces, with relatively little emphasis on the role of public policy. They have described the effect of population densities on agricultural intensification assuming a benign or at least policy-neutral environment. This paper departs from the conventional view and demonstrates that a policy-led approach to intensification is critical to maintaining and preserving resources otherwise degraded through more intensive use. It argues that autonomous intensification, the result of population growth on factor scarcity and the freeplay of market forces, is by itself unlikely to achieve the expected gains in per capita agricultural production and rural income.

In the study, the environmental consequences of growing population pressure without gains in agricultural productivity in six Sub-Saharan African countries are documented.[1] The paper demonstrates that the most pragmatic means of achieving rapid growth in agricultural production, employment, and incomes in circumstances of rapid population growth and declining extensive margin is to focus resources and policy attention on areas most responsive to chemical fertilizers and improved seed (see also Lele, Christiansen, and Kadiresan 1989). *Raising agricultural productivity in such areas offers the prospect of achieving quicker relief to the environmental problems such as soil depletion and deforestation.* The faster the improvement in factor productivity, the smaller the proportion of land and population needed for employment in agriculture to feed the total population and the greater the possibility that increased area can be left fallow or reforested. Given the higher rates of population growth and the absence of options to migrate, the movement to enhanced productivity will hinge on policy-led initiatives.

In the past, political pressures within countries to spread resources and government services to as much of the population as possible after independence led to the expansion of development projects in virtually all parts of the countries. The equity and food security concerns of the donor community in the 1970s also led it to support development projects in areas of marginal physical potential and indeed even in the areas of medium potential in support of subsistence food crops (Lele 1988a). The result for many countries has been *a regional redistribution of production but without substantial growth.* Thus to effectively address both growth and equity concerns in Africa—while simultaneously conserving the environment—will require both active production policies to stimulate growth in areas of high potential *and* consumption and welfare oriented efforts in areas of lower productive potential. Focusing on high potential areas alone risks increasing regional inequalities, as weak transport networks can prevent markets from functioning, integrating effectively, and allowing marginal areas to share in the gains. Alternatively, attempts to develop areas of lower productive potential, while justifiable on grounds of nation-building and encouraging participation of all groups in economic growth, carry implicit economic costs that must be recognized. Finally, in areas of lower potential but high densities (such as in northern Nigeria) or remote but productive areas (such as the Southern Highlands of Tanzania) development policies must inevitably be accompanied by a willingness to tolerate slower growth while an appropriately targeted long-term strategy is given a chance to work.

Agricultural Intensification: What Does it Mean?

Defining Intensification

Agricultural intensification is traditionally associated with changes in land use and fallow periods. Following Joosten (1962), Ruthenberg (1980) defines the intensity of cultivation, among other ways, by measuring the length of fallow periods between plantings.[2] Ester Boserup (1965, 1981), whose work forms a theoretical foundation for the hypothesis, also argues that as the population density increases, changes occur in cropping techniques such as first expanding the area under cultivation, or when that is no longer possible, shortening fallow periods and increasing the labor input to satisfy the higher demand for food. The theory rests on the assumption that the "problem" of population pressure gives rise to its own solution; the very scarcity of land, by altering factor prices, results in its more intensive use.

Two basic concepts integral to the Boserup hypothesis are factor substitution and technological change. Rising opportunity costs of holding land fallow are compensated for by working the land harder, often with decreasing returns from each additional unit of labor. Instead of a "peak season" for agricultural labor, the shift to intensive agriculture implies year-round activities such as water collection, soil management practices, and staggered crop production. The surplus generated from more intensely cultivated land contributes to growth in other sectors through linkage effects in infrastructure, markets, credit, and services. This view of intensification is further elaborated by Binswanger, Pingali, and Bigot (1986) and is consistent with the "induced innovation" argument presented by Hayami and Ruttan (1985), who contend that changes in factor proportions will lead to conservation of the more scarce resource—in the case of several MADIA countries, land—and to increased use of the abundant resource in production—in this case, labor.

A critical dimension to Boserup's model of intensification is that the higher population densities increase agricultural production and off-set the diminishing returns to inputs on a fixed land base. Thus, even though the regenerative fallow cycle that restores organic matter to the soil may *initially* be abandoned, savings from higher output can later be reinvested in land, labor, and tools to keep soil productivity high and prompt growth in other sectors of the economy. The assumption of induced innovation in situations of extremely high population growth rates, however, may not be valid. In the face of high population growth from preexisting high levels of population density, the externalities of agricultural research to bring about technical change will require an active public role (Lele, Kinsey, and Obeya 1989).

Two important dynamics are simultaneously at work. The first concerns changes in cropping patterns occurring more or less *autonomously* in response to population pressure, or persons per square kilometer. (Cultivable land per capita is also considered as an indication of population pressure. Available agricultural land per person is often less than densities might reveal due to semiarid conditions.) These "pressures" are normally reflected in the frequency with which land is cropped. The second, perhaps unforeseen, dynamic concerns the damaging effects of rapid population growth on the environment. This occurs when the positive effects of population growth (as seen in the more intensive use of land) are superseded by the detrimental effects of continuous cropping (soil degradation and fertility loss) and deforestation. This is an especially serious problem given the fragile nature of African soils, their dependence on vegetative cover for moisture and stability, and the effects of continuous cultivation. Recent data show, for example, that for each 4,000 kilogram crop of maize produced on a hectare, 200 kilograms of nitrogen, 80 kilograms of phosphate, and 160 kilograms of potassium are removed from the soil (Higgins, personal communication). Other agronomists, while conceding these general effects, question the magnitude of losses being claimed, but few systematic studies exist that analyze these long-term effects. It seems clear that the role of policy in channeling "autonomous" forces and their long-term effects on the environment may be understated in Boserup's work. Developing countries facing heavy population pressure must adopt a strategy for *policy-led* intensification. This is a particularly serious issue in Africa. Not only is the environment more fragile, but the capacity of the governments to put together complex and finely-tuned packages to meet the diverse needs of a large number of small farmers and achieve marginal improvements in productivity is limited, especially in view of the lack of a clear consensus on appropriate policy. There is an acute need for policies that promote the interests of small farmers to ensure broad participation in economic growth.

Intensification of agriculture in this paper is therefore considered somewhat differently than in the Boserup-related literature, in that it considers *output* as well as changes in the length of fallow period. It can be measured in three interrelated ways: a shift from low to high value crops on any given land; increases in yield per hectare of any given crop; and a geographical shift in crop production from areas of poor potential to those of higher potential. Over the period 1960-1987, the three countries experiencing the fastest growth in per capita GNP—Cameroon, Kenya, and Malawi—achieved their growth not through increases in productivity, but through shifts to higher value crops (coffee and maize in Kenya being exceptions to this rule) (Lele Forthcoming). With less land available for expanding area under crops, especially high value crops, more attention and hard empirical study will have to be applied to the task of raising productivity in the agricultural sector. Research carried out in the MADIA study indicates that with increasing population pressure and the movement of people into marginal areas (reducing average yields), an increasing proportion of land in many countries is being allocated to food crop production. The number of people dependent on the market for food, even in rural areas, is increasing rapidly. There are very clear signs of reduced soil fertility and declining rainfall (Lele, Christiansen, and Kadiresan 1989). While some question the extent of decline in soil fertility, the relationship of reduced rainfall to environmental stress, or the decline in rainfall, they concede that more often than not public policy stands in the way of the shift to higher value crops, to increased input use or improved resource management that would otherwise occur. In Malawi, for instance, the practice of issuing licenses

prohibits smallholders from producing burley tobacco, a lucrative crop on the world market that is reserved exclusively for estate production.[3] It is not known, however, how unique the case of Malawi is. Another constraint is land policy. In Kenya and Malawi, having either no access to capital or constrained by ethnic and cultural barriers to land acquisition, many people are forced onto marginal land. Finally, initiatives to develop national research capacity, such as the programs in Senegal and Malawi, are focusing first on investment in large physical capital and technical assistance; their emphasis on the substance of agricultural research issues and on building human capital resources or developing seeds, fertilizers, and farm management practices appropriate to specific physical circumstances and requirements of low income households is relatively weak.

In defining intensification, the crucial issue is not the frequency of cropping, which with population pressure appears inevitable. That frequency is instead only one of many determinant variables, which include the choice of crops actually grown, the quality of land designated for cultivation, the permission to grow high value crops, and the size of output (and the market where it can be sold).

Limitations of the Hypothesis

In this section we briefly outline the first dynamic inherent in autonomous changes in cropping patterns outlined in the Boserup hypothesis and point out its limitations before taking up the second dynamic of environmental damage and its implication for policy.

The direct bearing of population density on frequency of land use is more obvious than the movement to higher levels of technology and more efficient resource use. The latter phenomenon is induced by what Pingali and Binswanger (1984) call "farmer-based innovation." It depicts the slow evolutionary process of adapting the means of production to changes in factor costs. As labor and credit, tools, and other inputs become less costly relative to land, the farmer will naturally select the cheapest combination of inputs that maximize output and lower his or her opportunity costs. However, the process of change is a slow one; Europe and Asia had centuries to perfect locally suited techniques of intensification to their high-density conditions. The relevant question in the context of Africa is whether the catalyzing factor of population is ahead of or behind the pace of farmer-based innovation. The question reveals a major limitation of the Boserup model. High rates of population growth in an initially high density area jeopardize the perceived benefits of autonomous intensification.

> ...the intensification of agriculture may compel cultivators and agricultural laborers to work harder and more regularly...[and] facilitates the division of labor and the spread of communications and education.... **This condition may not be fulfilled in densely peopled communities if rates of population growth are high.** (Boserup 1965, p. 118). (emphasis added)

Rapid population growth eats away at capital savings and investment and the physical resource base. That this is arguably the case in many parts of Africa constitutes a primary reason to try to extend Boserup's original hypothesis.

Another obvious limitation of the model is revealed when countries are confronted with a diminishing land frontier and none of the expected gains from population growth. Boserup explains that the high population density is a precondition of technological change, but it alone does *not* insure that new techniques will be adopted.

> If it is true, as suggested here, that certain types of technical change will occur only when a certain density of population has been reached, it of course does not follow, conversely, that this technical change will occur whenever the demographic prerequisite is present. It has no doubt happened in many cases that a population, faced with a critically increasing density was without knowledge of any types of fertilization techniques. They might then shorten the period of fallow without any other changes in methods. **This constellation would typically lead to a decline of crop yields and sometimes to an exhaustion of land resources. The population would then have to face the choice between starvation and migration** (Boserup 1965, p. 41). (emphasis added)

Whereas in the process of autonomous intensification that occurred in Europe and Asia the option to migrate was more widely available, especially to overseas colonies, in the case of many countries in Africa it seems no longer a viable solution. It is for this reason that agriculture and research policy must concern itself with the environment.

While acknowledging their intellectual debt to Boserup, Pingali and Binswanger (1984) also express skepticism about the situation in Sub-Saharan Africa. They observe that farmer-based innovations appear to be "incapable of supporting rapidly rising agricultural populations and/or rapidly rising non-agricultural demand for food." Furthermore, they suggest that "large-scale irrigation systems and science- and industry-based technical changes must become major sources of the rate of growth in agricultural output" (1984, p.2). Science- and industry-based innovations include technological and mechanical inputs that can be administered or overseen by the state to speed up the "natural" process of farmer-based innovations. Even though large-scale irrigation for the most part has turned out to be costly and difficult to maintain in Kenya, Nigeria, and Senegal, the point that the state must take the initiative in exploring, maintaining, and conserving resources is well taken.[4] Elsewhere the MADIA study documents the benefits of promoting small farmer organizations for the development of low-cost irrigation as a viable alternative to the more costly large-scale irrigation projects previously desired by governments and donors. However, potential for even small-scale irrigation is not fully known, and existing information suggests it to be much more limited in Africa (5 percent of total cultivated area in Nigeria is irrigated) than in Asia (where irrigated area represents 22 percent in India and 28 percent in Indonesia) (Lele and Meyers 1986; Lele, Oyejide, et al. 1989; Lele 1988a).

"Speeding up" the natural evolution of intensification is a complex task, especially for Africa's relatively young state bureaucracies. A crucial distinction separating Binswanger and Pingali from Boserup is their greater attention to policy and the role the state must play to encourage intensification. In addition to identifying salient technological priorities for Sub-Saharan Africa, they also warn that:

> ...the transition to these new technologies depends on many factors—the relative cost of labor, capital, and fertilizers; the cost and availability of credit; the reliability of markets for inputs and output; the access to spare parts and repair facilities; and the adequacy of information and training systems (Binswanger and Pingali 1988, p.84).

A successful transition to more intensive (i.e., sustainable) use of the land thus depends largely on the specifics of sectoral policies toward agriculture. Besides population densities, Boserup (1981) introduces other variables into her original formulation of the hypothesis to explain the weak showing of autonomous intensification in Africa; these include lack of infrastructure, inefficient extension and marketing, and rural-urban migration. A formal reading of her previous work suggests that these constraints would be lifted as population grew and new technologies were adopted. Our research indicates that they persist and indeed become compounded with population growth and high population densities, especially in circumstances where there is no correspondence between population densities and land quality.

The second, related dynamic that does not receive enough attention concerns, among other things, changes in soil quality as land is cropped more intensively. Boserup notes that when "the analysis is based on the concept of frequency of cropping, there can be no temptation to regard soil fertility exclusively as a gift of nature bestowed upon certain lands once and for all" (Boserup 1965, p. 15). She argues quite rightly that the soils' structure and nutrient levels will depend not only on initial status but also on the farming techniques selected. However, it is almost implicitly assumed that in the transition from extensive to intensive cultivation the farmer will invest more in labor (mulching, terracing) to minimize the negative effects of continuous cropping.[5]

A more realistic assessment may be that in the short-run not only does it makes economic sense to "mine" the land but also it may be inevitable. Ruthenberg, for instance, remarks that an agricultural surplus in the industrial countries came from the "exploitation of natural resources in terms of nutrients and humus which were used to feed laborers cheaply to facilitate industrial capital formation" (1980, p. 12). He argues that whereas the process of soil mining in the industrialized countries was accompanied by the accumulation of a surplus, in developing countries the practice is employed merely to maintain current levels of consumption. The natural process of intensification is far too slow in relation to the rate of mining, given the rapid growth of population. As pointed out earlier, according to the FAO, such soil mining is occurring in Africa on a large scale, causing much more irreparable damage than would be the case with soils in temperate climates, which tend to be structurally more sound (Higgins, personal communication).

Similarly, shifts onto marginal areas and stagnating overall crop yields may signal that intensification in terms of frequency of cropping is occurring, but that the envisioned reinvestments into productive assets (e.g., the land) are not.[6] In Kenya, for example, the fastest population growth between 1969 and 1979 occurred within those provinces (aside from Nairobi) that were least populated and least fertile, including districts in the North-Eastern, Rift Valley, Eastern, and Coast provinces (see figure 1). The provinces that grew least had the highest initial densities, suggesting a spillover effect into Kenya's less densely inhabited but more marginal regions. If the intensive margin in the high density area yields a lower return than the extensive margin in the low density area, a resource shift (including population) to the latter area is appropriate, but this has not been empirically established. Given the rising demographic pressure developing in low income areas, the environment may prove to be the weak link in the chain binding population densities to autonomous agricultural intensification. This paper argues that it is the government's role to reinforce that link with appropriate institutional and policy support.

Present and Projected Land Availability

Although the primary focus of this paper concerns policy measures available to tap *regional* advantage in cropping, an overview of the land constraints facing Kenya, Malawi, Tanzania, Cameroon, Nigeria, and Senegal will provide an idea of the urgency with which these issues must be addressed. In the discussion that follows, for more detailed information on disaggregated data, the reader is referred to the statistical annexes.

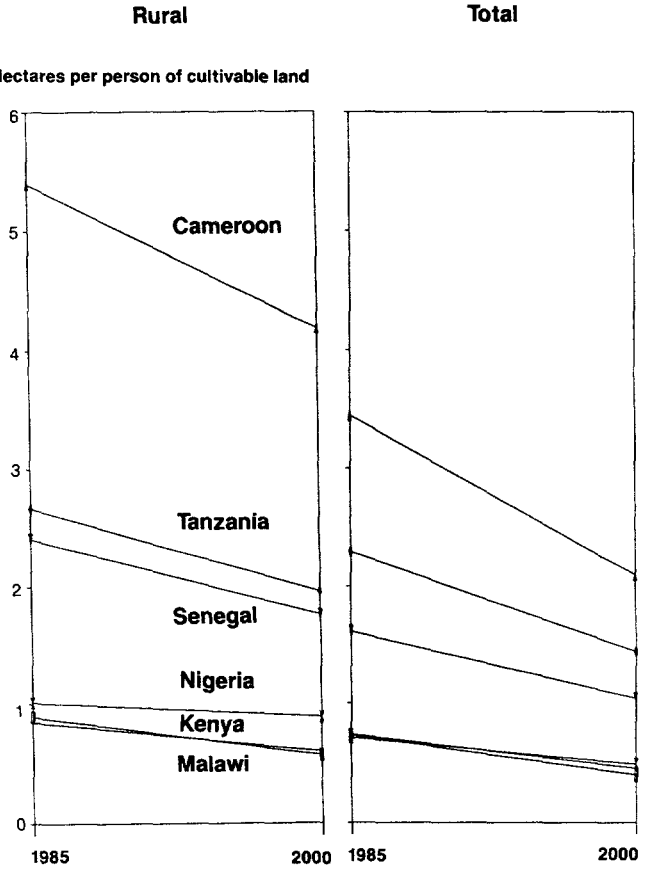
Introduction

In most MADIA countries, population has doubled since the independence period, and will double again shortly after the turn of the century. Yet even though population densities have reached quite high levels in some parts of Africa—up to 300 persons per square kilometer in the highlands of Kenya, in southern Malawi, and in coastal Nigeria—it is unclear whether reinvestments in land and labor are occurring in compensation. A very important consequence of higher density is that as the share of population depending on the market for food increases, including those moving to marginal land, the internal terms of trade move in favor of food crops (Lele 1988a). In theory growth in food imports should keep up with internal demand growth. However, in practice import capacity tends to be limited at early stages of development by slow growth of exports. Policies toward exchange rates and taxation of crops can make a significant difference in the speed at which relative prices between food and export crops move, but they may not be able to avert this shift altogether. This is especially true when the price of imported food increases with devaluation and population growth reduces land productivity while simultaneously increasing the demand for food. As relative prices shift, agricultural production moves away from traditionally high value export crops, posing a potential problem in the move to intensification as we have defined it.

At present, Kenya, Malawi, Nigeria and, to a lesser extent, Senegal are experiencing substantial population pressure. The first three countries constitute 75 percent of the MADIA population and 30 percent of the total population in Sub-Saharan Africa. By government definitions, not one of them currently has more than three-quarters of a hectare of cultivable land per person (using total population). By FAO definitions, the per capita amounts are even *smaller*. Projecting to the year 2000, this figure will fall to less than half a hectare (see Figure 2) and to a miniscule 0.1 hectare per person in parts of Kenya, Malawi, and Nigeria (see Annexes 4, 5, and 6). Using only rural population to calculate the figures improves the ratio of people to land (especially in the more urbanized West African countries) but does not relieve the demand for food or lessen the degree of population pressure (see Table 3).

The per capita land figures are deceptive, however, in that they mask very important differences in land quality and in regional concentrations of population. It is noteworthy that even in land-surplus countries, population is concentrated on small amounts of land. In Cameroon, for instance, millions of hectares of well-watered land in the eastern tropical rainforests go unused while population pressure and declining rainfall in the semiarid Far North and North provinces have already begun to threaten fragile ecologies. The causes manifest in decreasing land availability are very much more complex than simple growth in population: they include such politically sensitive issues as the original expropriation of land by colonials and its subsequent transfer to elites, policy bias toward estate agriculture, health factors such as river blindness, tsetse infestation in more watered areas, and ethnic discrimination.[7] These and other factors can prevent the shift to more productive land. Such is the case in Senegal, where the predominance of the Mandinque tribe in Casamance presents an obstacle to Wolof migration from the crowded and less productive Groundnut Basin and in the Middle Belt of Nigeria, which has more assured rainfall and greater fertilizer responses but low densities. This section can only

Figure 2
"Arable" land per capita in the MADIA countries, rural and total populations, 1985 and 2000



Note: A similar graph was used by Binswanger and Pingali (1988) using agroclimatic densities, based on FAO/UNFPA/IIASA figures (Higgins 1982). The figures presented here are per capita amounts of arable land based strictly on government definitions. For treatment of FAO/UNFPA/IIASA findings, see Section 3.
Source: Government data (see Tables 2 and 3).

indicate the broad *statistical* parameters of the problem.

Because of these complexities, the regional dimension of policy-led intensification, in terms of where governments have been and should be investing their resources, should form the substance of policy debate. It makes a big difference whether populations are concentrated in areas of high or low potential, and whether the emphasis is on long- or short-term gains. If reaching the most people and increasing production with the quickest return on investment is the priority, it obviously makes sense to focus resources on high-density, "high-potential" areas. By the same token, it may then be essential to have education, employment, income, and consumption policies that protect those in the low potential areas. It is to the exploration of these issues that we now turn.

Aggregate Land Availability

There are vast differences in the amount of land classified as "arable" in Sub-Saharan Africa, ranging from 26 percent in Kenya to 75 percent in Cameroon and Nigeria. For Kenya, this means discounting the 400,000 square kilometers of land that receives less than 300 mm of rainfall per year and is considered barren (see Figure 3). Apart from variations in climate, these differences also result from methodology in land classification. Kenya's figure reflects a detailed analysis of agroclimatic growing zones and land potential for the entire country, carried out by the Ministry of Agriculture and the German Agency for Technical Cooperation (GTZ/ Jaetzold and Schmidt 1982). As a result, their estimate of 26 percent arable is thought to be quite reliable. In the cases of Nigeria and Cameroon, by contrast, government estimates of arable land are based on less extensive analysis and tend to be more optimistic.[8] The more accurate information on land availability makes it easier to assess the land constraint on a regional basis, and therefore to determine where to focus resources for intensification. For many countries in the MADIA sample and elsewhere in Africa, however, there is very little authoritative information on either land quality or land availability. Effective policy will depend directly on the quality of information about land as it becomes more scarce.

The extreme diversity in land quality between countries can be seen by comparing estimates of overall land availability. For example, Table 1 (and Figure 4) shows that, at any given level of population, there are dramatic differences between total land and arable land area. Land unsuitable for cultivation is considered to be quite high at 74 percent of the total in Kenya, 47 percent in Senegal, and 44 percent in both Malawi and Tanzania.

Second, Table 1 indicates that using "arable" as a generic term to mean "cultivable" can be misleading. The FAO (Production Yearbook) definition of arable land excludes areas under permanent pastures or permanent crops, forests/woodlands, and "other" land, and therefore reflects

Figure 3
Classification of arable land in Kenya

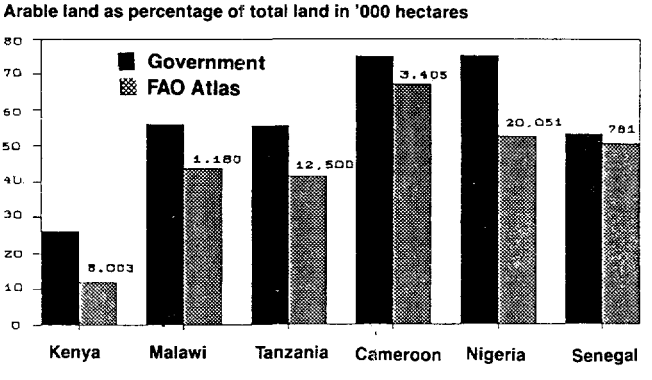
Figure 4
Differences in arable land by country and source



Source: National Estimates (Table 2 and 3) and FAO *Atlas of African Agriculture* 1986b.

cultivated rather than *cultivable* land (FAO 1986a). Most governments, however, choose to include forests and permanent crops in their definitions as it yields a more generous estimate of arable land. Using the government figures sheds a more optimistic light on the room left for "extensification" than seems desirable from an environmen-

Table 1
Comparison of total land and arable land per capita availability, 1984 (government and *FAO Production Yearbook* definitions in hectares per person)

Item	Kenya	Malawi	Tanzania	Cameroon	Nigeria	Senegal
Per Capita						
Total land	2.79	1.31	4.13	4.59	0.94	3.04
Arable land (government)	0.73	0.73	2.30	3.45	0.71	1.62
Arable land (FAO)	0.09	0.32	0.19	0.58	0.30	0.81

tal point of view. Clearing forests has direct ecological consequences on the long-term effectiveness of intensification; whether rainforests, tropical cover, or bush trees are removed, the effect is to destabilize soils and render them more vulnerable to wind and water erosion. The distinction between forests and potentially cultivable land also underscores the crucial omission of environmental sustainability that needs to be added to the list of Boserup's original concerns.[9]

More recently the FAO published an *Atlas of African Agriculture* (1986), which lists "potentially cultivable" land figures that appear to share the broader definition used by government sources (see Table 2). In most cases, the Atlas figures are *still* more cautious about the absolute size of the available land base than are national estimates (see Figure 4). In Nigeria, the difference between the two estimates is on the order of 20 million hectares, or one-quarter of total land area. In Kenya, the new FAO figure is less than half of the national estimate. In Tanzania, the FAO Atlas figure is also 12 million hectares less than the government estimate, while in Malawi, the FAO estimate is about 1 million hectares—or 12 percent of total area—shy of government figures. Despite the lack of consensus over how much land is actually available for farming—in Malawi, government estimates have ranged from 19 to 56 percent of total area[10]—it is clear that using FAO figures merely increases the urgency for a policy-led intensification, including among other things the fundamental importance of improving the land statistics.

A final important point must be made before leaving this section. Elsewhere it has been documented (Lele and Meyers 1986; Oram 1987) that gains in agricultural output in the past few decades have come from increasing the area under cultivation.[11] According to the FAO Atlas, up to two-thirds of total cultivable land for Kenya, Malawi, and Nigeria is already in use (see Figure 5). When available, government data appear to confirm this trend: in the Groundnut Basin in Senegal, for instance, area under crops reached 70 to 80 percent of total cultivable area in 1976, the last year for which such data are available (see Annex 3). Likewise, government surveys in Malawi indicate that 60 to 70 percent of the declining amount of customary cultivable

land under the control of the Malawian smallholder population in the more crowded agricultural development districts (ADDs) of Blantyre and Lilongwe were already under crops in 1985 (see Annex 5). As more area comes under crops and is cultivated more frequently, soil degradation and ultimately complete loss of fertility become more likely. This is the most compelling evidence for policy-led intensification; the area frontier acts more or less like an hourglass by which to gauge the time remaining for autonomous intensification.

Aggregate Population Data

Population data (using government estimates) were held constant in the preceding calculation of per capita arable land to highlight differences between FAO and government estimates of land availability at the national level. Nonetheless, wide differences also exist in the population data. Ethnicity and population growth are much more explosive issues in some countries than in others and affect statistics differently. Whereas Kenya and Malawi have routinely published data on changes in the ethnic composition of the population, a census cannot be conducted in Nigeria because the publication of such information might spark a political controversy. Cameroon and Senegal did not conduct national censuses in the 1960s, and Nigeria has not conducted a census since 1963.[12] The 1963 census figures were themselves considered overinflated, with the result that government and World Bank projections to the year 2000 differ by as much as 16 percent, or 23 million persons. The lack of agreement between population estimates is reflected in Table 3.

Despite the inconsistencies in data, overall high rates of population growth—generally about 3 percent a year and around 4 percent in Kenya—leave little room for doubt about growing demographic pressure on the resource base. Table 4 shows that rates of population growth have risen in all cases since the 1960s, and are projected to continue at high rates through the year 2000. The question of how to effectively channel new demands for land, food, income, and fuel into a productive force for development becomes all the more pertinent in view of the limitations of the Boserup model and the inadequacy of autonomous intensification to accommodate high rates of growth.

Urbanization is more advanced in West Africa, where about one-third of the population lives in cities and towns of at least 5,000 persons, but rates of growth in urbanization are much higher in East Africa.[13] For Cameroon, Nigeria, and Senegal, the urban population is projected to increase by 5.7, 5.4, and 4.5 percent a year, respectively, from 1985 to 2000, whereas in East Africa, the urban populations in Kenya, Malawi, and Tanzania are expected to grow by 7.0, 8.3 and 7.6 percent a year, respectively (see Annex 7). Very little is known about the important subject of rural migration or the nature of the rural/urban/rural migration in most MADIA countries, with the exception of Kenya and Malawi, which have much better data than the other countries. Migration away from agriculture can relieve on-land pressure in per capita terms, but if there is no technological change in agriculture that increases labor productivity, increased urbanization only changes the terms of trade in favor of the food crop sector (Lele, Oyejide, et al. 1989).

Estimated Carrying Capacities[14]

The FAO, in coordination with the United Nations Fund For Population Activities (UNFPA) and the International Institute for Applied Systems Analysis (IIASA), has calculated the maximum amount of calories that could be produced in each country to determine its carrying capacity, based on agroclimatic conditions and varying levels of input use.[15] The results are necessarily rough, because they rely on a technical rather than a social estimation of ideal

Table 3

[ff] Rural population derived from urbanization estimates for 1965 (27 percent) and 1985 (36 percent) (World Bank 1987) to get rate of 1.45 percent, projected to 2000 from 1982 level of urbanization.

crop allocation. Despite inaccuracies, the study is important as the first and only systematic attempt to quantify land potential in Africa. The results have been applied in many forms (Binswanger and Pingali 1988; Oram 1987) and are highly relevant to our current study.

The evidence presented in the FAO/UNFPA/IIASA study on carrying capacities suggests that of the six MADIA countries, Kenya is least able to produce enough food at low input levels to sustain its present and projected population. Looking strictly at arable land availability using government definitions, we find that Malawi, Nigeria, and to a lesser extent Senegal all face similar land constraints. The study results are complicated by the various assumptions used in the assessments, which include production from rangelands and fallow lands.

The most meaningful way of interpreting FAO's assessment is to use the data for carrying capacities from rainfed lands alone and to translate them into terms of *minimum*

Table 4
Rates of growth in population, 1960-2000 (in percent per annum)

Country	1960-70	1970-82	1980-86	1986-2000 (Projected)
Kenya	3.2	4.0	4.1	3.9
Malawi	2.8	3.0	3.2	3.3
Tanzania	2.7	3.4	3.5	3.4
Cameroon	2.0	3.0	3.2	3.3
Nigeria	2.5	2.6	3.3	3.3
Senegal	2.3	2.7	2.9	3.0

Note: The Nigerian government uses the rate of 4.0 percent growth for Lagos and 2.5 percent for the rest of the country. As a result its estimates are 16 percent lower than the Bank's for the year 2000.
Source: World Bank 1984; 1988.

amounts of rainfed arable land required to support one person. A *minimum land requirement* indicates the relative average productivity of the land, based on FAO/UNFPA/IIASA assumptions.[16] We compare these figures with those we have already calculated, the government-estimated amounts of arable land available per person. The results are presented below. One observes that for Kenya, Senegal, and Nigeria, the minimum "low-input" requirement is greater than the 1985 per capita available land and that this situation will extend to Malawi by 2000. Only with increased input levels and/or major land improvements (such as irrigation) will these countries be able to meet food needs on a sustainable basis. Another possible way of interpreting the results is that growing conditions, including land quality, are poorest in Kenya and Senegal because minimum rainfed land requirements are highest there.

Table 5
Per capita land requirements and land availability, rainfed arable land (in hectares per person)

	Rainfed land requirement		Available rainfed land (government estimate)	
Country	Low Inputs	Intermediate Inputs	1985	2000
Kenya	2.8	0.6	0.7	0.4
Senegal	2.7	0.5	1.6	1.0
Tanzania	1.1	0.3	2.3	1.4
Nigeria	0.9	0.2	0.7	0.5
Malawi	0.6	0.2	0.7	0.5
Cameroon	0.4	0.2	3.5	2.1

Source: FAO 1978; National Data (see Tables 2 and 3).

At first sight such a conclusion is counterintuitive. Who would imagine the more fertile parts of Kenya to just be reaching par with areas in Nigeria, Tanzania, or Malawi? A look at two further sets of data, however, confirm this view. First, a comparison of the proportion of cultivable land occurring in the subhumid or humid tropics shows how "moisture" advantaged countries such as Cameroon and Malawi are in comparison with Kenya and Senegal. In such moist environments, double cropping (e.g., of rainfed rice) is a possibility, and hence the FAO/UNFPA/IIASA study accords them a higher value than areas where only a single rainfed crop can be grown. Data showing the percentage of total cultivable area formed by subhumid and humid cultivable tropical areas are shown below:

Kenya	Senegal	Tanzania	Nigeria	Malawi	Cameroon
10%	30%	51%	60%	64%	91%

Second, a look at response coefficients for food crops provides further support. Although coefficients of variation, length of growth cycles, and rainfall dependability vary between Kenya and Nigeria, the high potential lands of Kenya appear roughly twice as responsive to fertilizer than land in Nigeria (see Table 6). The MADIA study on fertilizer documents in detail the range of response coefficients by ecological zones and population densities (Lele, Christiansen, and Kadiresan 1989).

A great deal of documentation accompanies these coefficients and so one should be cautious about generalizing them. The responses for Kenya, for instance, refer to the so-called high potential areas that receive high levels of moisture and enjoy deep, fertile soils. Since 74 percent of the land in Kenya is arid, however, carrying capacities as

Table 6
Fertilizer response coefficients for hybrid maize in Kenya, Malawi, Tanzania, and Nigeria

Source	Kenya	Malawi	Tanzania	Nigeria

calculated by FAO/UNFPA/IIASA are higher on average in Tanzania, Nigeria, Malawi, and Cameroon on an *aggregate* basis. Obviously, some parts of Kenya and other countries will be much more productive in certain crops than will others. We turn briefly to an analysis of regional cropping patterns, rainfall, and population densities before closing the section on aggregate data with a look at deforestation.

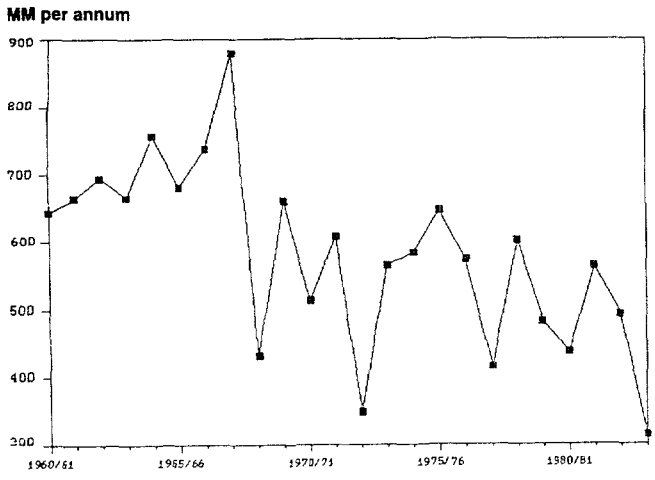
Soil and Rainfall Constraints

This section points out some sources in the literature for analyses on climate and soils in Africa. It cannot be authoritative, but will try to indicate prominent research and its relevance to intensification. In addition, it attempts to correlate population densities and rainfall, and rainfall level and production possibilities. Production possibilities afforded by the resource endowments of a given country determine the income opportunities available to different regions. A region's comparative advantage in growing high value crops such as tea, coffee, or cocoa can increase foreign exchange earnings, employment, and income to the benefit of different groups. It can speed the process of intensification, depending on price incentives and investments in government services. On the other hand, equity concerns may overshadow the investment and price incentives governments are willing to allow particular regions, especially if regional income inequalities threaten political stability.

It has been observed by Matlon (1987) that the soils of West African semiarid tropics and parts of the humid and subhumid tropics farther south are far more susceptible to rapid degradation with continuous use than was previously thought. Low and variable rainfall makes intensifying fertilizer use a risky and sometimes marginally productive proposition, especially in Sahelian countries such as Senegal, where fertilizer application can go unused in a dry season or can be washed away in a sudden downfall (see Figure 6). Even in eastern and southern Africa, considered to have slightly more stable agroclimatic conditions, increasing frequency of cropping and shorter fallow periods are reducing the soil's fertility and undermining its nutrient content. The process of degradation has accelerated as more people are moving onto marginal land with long fallow requirements.[17] These conditions complicate the evolutionary movement toward higher levels of technology and weaken the causal linkage between increasing population densities and agricultural output implicit in the Boserup hypothesis.

Broadly speaking, in the semiarid tropics of West Africa between the 200 and 800 millimeter isohyets (8 to 20 inches—see map), crop production is generally limited to lower value commodities through systems of mixed cropping: sorghum/millet, groundnuts, and cotton. According to some, research priorities in these areas (central and northern Senegal, northern Nigeria, and Far North Cameroon) should focus on faster maturing varieties that can

Figure 6
Mean annual rainfall in Senegal, 1960-84



Source: DPGA 1961-85.

deliver stable yields in the face of declining or erratic growing seasons (Oram 1987). A counter argument is that in the case of sorghum, early-maturing varieties conflict with traditional mixed cropping with millet and may even impair yields if they flower before the rainy season ends (Lele, Oyejide, et al. 1989).

In higher rainfall regions, between the 800 and 1000 millimeter isohyets (see map), soils are typically ferruginous, crusty, and prone to leaching. Clay content is generally below 20 percent (Matlon 1987). As a result, these soils tend to be shallow and have low natural fertility and poor moisture retaining capacity, as opposed to soils containing more clay or organic matter. Crop production in this climate, extending into southern Senegal, the Middle Belt states of Nigeria, and northern Cameroon, include more cereals such as wheat and maize and a variety of tubers such as yams and cassava. Soils are by comparison much more fertile in the Asian semiarid tropics (Matlon 1987). As a result, response coefficients to fertilizer tend to be low in many parts of tropical Africa and crop research must begin to consider new ways of maintaining soil fertility and increasing output. Even so, fertilizer response is higher than in the drier northern regions, indicating an untapped potential. The threat of trypanosomiasis, as well as other pests and diseases, prevents the extensive use of draft animals in the humid and subhumid tropical regions, and keeps population densities low, despite apparently higher potential for a wider range of crops than is possible in the North.

Eastward and to the South, in the lower parts of Nigeria and Cameroon, one finds similar problems with soils in the humid and subhumid tropics. Greater moisture and rainfall do not translate into better growing conditions. One popular study notes:

> Rainfall in tropical areas generally is highly erosive. Rain causes erosion when it falls at more than 25mm an hour. Only five percent of rainfall in temperate areas is erosive. The proportion in tropical areas is around forty percent—much of that at even higher and more destructive velocities. Downbursts of 100-150mm an hour are not uncommon—as much rain as New York gets in an average month (Harrison 1987, p. 36).

Soils with few exceptions are vulnerable to acidification and other factors, have poor structural stability, and when cultivated intensively will be more susceptible to erosion. Likewise the removal of tree cover has grave implications for the structural stability of these soils. The problems of soil degradation and erosion are especially acute in this zone owing to high population densities, e.g., in Nigeria. Some of the more interesting material still in experimental stages coming out of the International Institute for Tropical Agriculture (IITA) in Nigeria to cope with these conditions includes alley cropping with leguminous trees and shrubs, new cassava varieties, and no-till cropping that increases soil fertility and retains vegetative cover, thus minimizing moisture loss and reducing erosion.

The higher level of rainfall in this area, between the 1400 and 3200 millimeter isohyets, is well suited to the production of tropical tree crops such as cocoa, oil palm, and rubber, and to the root crops yams and cassava. The higher returns per hectare from the higher value crops, assuming adequate yields in the humid and subhumid zones, give the government greater latitude in shaping its intensification strategy.[18] High value crops such as cocoa enable the government to extract a margin and still pass along profit to farmers; Cameroon is a case in point. Likewise, in Nigeria returns from planting improved cocoa were fully competitive with wages outside the agricultural sector even at the peak of the oil boom, but policy and institutional constraints inhibited expansion of new cocoa plantings (Lele, Oyejide, et al. 1989). The MADIA paper on fertilizer (Lele, Christiansen, and Kadiresan 1989) explains how exploiting regional comparative advantage is constrained by high costs of internal transportation and political and institutional barriers.

In East Africa, below 400 millimeters of rainfall, few crops other than sorghum and millet can survive; the diet is supplemented by livestock products such as meat, milk, and blood. Between the 400 and 800 millimeter isohyets, including large parts of Kenya and Tanzania, crop production is again limited to hardy and quickly maturing cereals like sorghum and millet, and to a smaller extent cotton, groundnuts, and tobacco. In regions with higher rainfall, between 800 and 1,200 millimeter isohyets, higher value grain crops like wheat and maize are possible, as is the production of tea, coffee, and pyrethrum in the higher altitude areas of East Africa (see map). The returns to labor per hectare are especially high for tea, coffee, and tobacco; but in Tanzania and Malawi, for instance, poor prices and other institutional constraints to export crop production have shifted incentives in favor of food crops. Other MADIA papers that address issues related to the development of cotton in anglophone and francophone Africa or structural adjustment in Malawi point out why, without intensification efforts on cotton in anglophone Africa or with improved maize in Malawi, the elasticity of acreage with respect to relative prices tends to explain much of the production response. These papers document how, with increasing population pressure and stagnant or declining yields, overall production increases are unlikely to occur simply through price corrections (Lele 1989a; Lele, van de Walle, and Gbetibouo 1989).

Soils in East Africa are thought to be structurally more sound than those in West Africa, but with the exception of subhumid highlands still thin and low in nutrients. They will initially give higher yields using higher inputs, such as chemical fertilizer, but will lose that capacity with repeated cultivation unless supplemented by organic matter, such as

animal manure or humus.[19] The need for constant biological input underlies the growing importance of agroforestry for farm management (Boehnert 1988). Tree cover also helps reduce high rates of water evaporation that shorten the effective growing season; solar radiation in East Africa (150-180 kcal per square centimeter annually) is the highest in the world (Collinson 1987). Low levels of rainfall and high rates of transpiration limit the utility of high solar intake, which more often than not just bakes the earth.

Deforestation

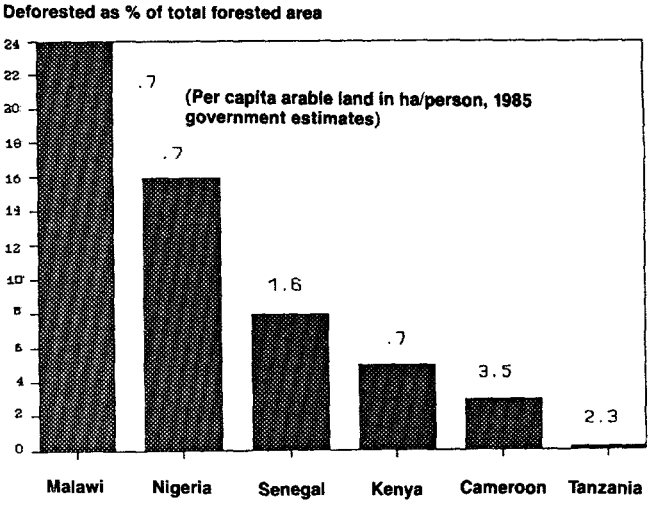
Deforestation relates back to the second, unforeseen dynamic of autonomous intensification. It represents an acute form of overexploitation of, rather than investment in, natural resources, contrary to the Boserup hypothesis. The central importance of forests for energy (fuelwood), for food (browse and fodder), and for environmental stability (soil and water retention), and their threatened position as the last easily accessible frontier for development, reinforce the argument for introducing a more comprehensive land policy to protect forests and encourage the use of trees in farming systems. This is why the FAO definition of arable land available for cultivation is of extreme relevance for policy governing the use of the forestry sector. Considering that fuelwood constitutes an estimated 90 to 95 percent of energy needs for rural populations in Sub-Saharan Africa and that it is also gathered for sale in urban areas, one would expect this resource to be in high demand in land-scarce countries and to observe a close correlation between population densities and a decline in forest area.[20]

The aggregate data presented in this section support this premise. The four countries under greatest population pressure correspond exactly to those suffering most from deforestation.[21] Nigeria, for instance, is often cited as a case where the sheer magnitude of deforestation is causing serious environmental damage. With only .71 hectares of arable land per person (by government definition), the country faces depletion of its tropical forest resources, as over one-quarter million hectares are cleared for agricultural and other uses *each year* (FAO 1981). Equally alarming in relative proportion is the case of Malawi, where population pressure is intense at just .73 hectares per capita of arable land. It is estimated that 120,000 hectares of woodland are cleared annually, almost half as much as is cleared in Nigeria on a yearly basis. If one extrapolates over 10 years, one finds that, because of its small size (91,000 square kilometers), Malawi faces losing up to 24 percent of its forest area in a decade (see Figure 7).

New recording methods should among other things consider removing this category from the calculations of arable land (as FAO Production Yearbook does); most governments—gauging by their definitions of arable land and vague or unarticulated policies—assume that forests can be brought under cultivation with relative ease and with few damaging consequences. A controversial issue is whether the Kenyan government's clearing of high altitude rainforest to make way for state tea plantations is causing permanent damage. Forest proponents argue that tree crops serve the double function of retaining soil cover and generating export revenues, but there is no consensus on the issue, nor is there likely to be until more research is completed.[22] Other high priority policy areas include promoting tree-planting campaigns at the national level and moving more land into state parks.

The role of forests extends well beyond being a source of

Figure 7
Deforestation in the MADIA countries relative to per capita cultivable land



Note: Includes broad-leaved, coniferous, and bamboo forests.
Source: FAO/UNEP 1981.

fuel and potential cropland; trees are an indispensable component of soil fertility management in tropical agriculture. In the drier Sahelian and Sudanian zones, for instance, it has been shown that trees not only protect soils against wind and water erosion and restore subsoil nutrients by shedding leaves, but they also provide fruits and leaves, firewood and building poles, bark for cord and medicine, and thorn branches for fencing, as well as serving as a critical source of browse for livestock in the dry season (Gorse and Steeds 1985). Forestry research in these climatic zones is said to be promising, including the use of plant tissue cultures for propagating well-suited clones and symbiotic root microorganisms to enhance the nitrogen-fixing capacity of certain species.[23] The importance of maintaining soil fertility and stability in the humid rainforest regions and the potential use of trees as part of integrated farming systems in the tropics have been pointed out previously.

What are the long-term effects of deforestation? The reduction of tropical, high altitude, and other forests has spawned a great deal of controversy. The Tropical Forest Resources Project undertaken by the FAO observes:

> One of the most serious consequences related to forest clearing is the loss of genetic plasma and of the seed bearers which leads to the complete disappearance of many species. On the contrary the impact of deforestation on the neighboring zones is much more complex to assess: changes in water regimes, erosion, climatic modifications, spreading of diseases, diffusion of polluting agents, change of carbon dioxide content of the air (FAO 1981).

Evidence turned up in the MADIA study points to marked changes in rainfall patterns over the past 20 years. For instance, annual rainfall in Senegal has decreased by 2.2 percent a year over the past two decades (Jammeh and Lele 1988). The MADIA studies of Nigeria and Cameroon also note a sharp decrease in rainfall in the northern parts of both countries (Lele, Oyejide, et al. 1989; Lele, van de

Walle, and Gbetibouo 1989). These trends are alarming in West Africa because of the more intense pressure on the land in the lower rainfall Sudano-Sahelian zones. Although these trends may be temporary, there is little evidence to suggest that they do not reflect a permanent change resulting from tree loss. Most will agree that consuming forest resources faster than they grow back is causing a slow but steadily growing environmental crisis.[24]

Slowly rising population densities may have once been enough in themselves to bring about positive changes associated with technological adaptation in production, resource conservation, and consumption behavior, but arguably this is no longer the case in Africa; the transition to high density populations has been too rapid. There has been little technological change in agriculture. The traditional farming systems of bush fallow were meant for low levels of population, not rapidly rising densities. They make the need for "intensification" and changes in farming systems more urgent. Limited resources, fragile ecosystems, and skewed incentives make it more difficult for the smallholder to plan beyond the subsistence horizon. They make the short-term overuse of resources such as trees and land rational, if only for immediate survival.

Land Policy

In this section a brief presentation is given of the various approaches taken toward land policy in the MADIA sample and the impact they have had on the intensification process. The analysis focuses on the East African countries as they have experienced the more rapid and abrupt changes in land tenure patterns; despite growing population pressure in at least two of the three countries, land in West Africa has been a surprisingly unimportant issue in public discussion and policy formulation.

In Kenya, land titles and licenses to grow export crops have been far more freely available than in Malawi, as shown by the fact that smallholder tea hectarage has increased almost tenfold and coffee hectarage doubled between 1970 and 1985 (Lele 1989). The World Bank has consistently supported land registration in Kenya, since the early 1960s. The amount of land registered in Kenya increased from 1.8 to 6.5 million hectares between 1970 and 1983, constituting 97 percent of all high and medium potential land, or, including semiarid and transitional areas, 44 percent of the cultivable land. The share of smallholders in total registered land was 43 percent overall, but it was well over 80 percent in Western, Nyanza, Central, and Eastern provinces, the heart of smallholder production areas in Kenya (Lele and Meyers 1987). Institutional rights to the land for smallholders have played a critical role in encouraging intensification, but differential access to institutional credit and a combination of social and ethnic factors have rendered the land market in Kenya imperfect.

In Malawi, customary rights to cultivate and transfer smallholder land are conferred by traditional tribal chiefs, while the expansion of estate agriculture has been determined by explicit government policies. Burley and flue-cured tobacco production has been reserved for estates through a licensing policy that accompanies the establishment of leaseholds on "unused" customary land. The transfer of land from smallholders to estates has contributed to economic growth through estate production but has worsened land distribution over time and led to a decline in average farm size in both sectors (Lele 1988a). Although the process of technical change may be slower for smallholders than for estates, land policy will be for Malawi one of the most important factors determining future growth in smallholder productivity (Lele and Agarwal 1989). Without a clear policy, a three-tier land ownership of estates, smallholders, and marginal or landless will emerge.

Similarly in Tanzania, smallholder control over land has suffered as a result of state policy. Tanzania formally abolished traditional tribal village authority, replacing it with public ownership of land whereby an individual has no right of ownership or sale. In fairness to Tanzania, it should be added that the World Bank's 1963 report provided a major intellectual justification for the so-called "transformation approach." The policy of forced "villagization" resulted in the resettlement of more than 9 million people—about 60 percent of the population—into 6,000 villages by mid-1975. Given the weak soils (the reason for traditionally sparser settlements), the Ujamaa policy toward land increased environmental stress and led to greater problems of erosion and deforestation (Lele, van de Walle, and Gbetibouo, 1989). Attempts at collective woodlots failed (according to one source because when one sites and plants a tree, it is tantamount to claiming ownership (Leach and Mearns 1988)), and production of wood-related crops like tobacco and pyrethrum has declined (Lele 1988a).

Interaction between Population Densities, Cultivable Area, and Land Productivity: Some Empirical Evidence

Distribution of Population on Land

A relevant question for designing a policy-led intensification strategy involves the location and degree of population concentration in relation to land quality. Are people more densely settled in the fertile "high potential" areas (defined by agricultural production and income possibilities), or are settlements—because of such factors as health hazards—located in drier areas of more limited crop production potential? To the extent that population densities are highest in the areas of high land potential, the answer will determine where future investment priorities in physical infrastructure such as roads, schools, clean water, and health facilities will have the greatest impact. Regional concentrations, and the land base beneath them, will also figure in policy discussions of where it makes most sense to promote the use of chemical fertilizers and to direct the efforts of agricultural research for the quickest returns.

This section therefore tries to sketch the proportions of population density on a regional basis and to assess the implications for development planning. Surprisingly, there is a high degree of population concentration in *both* land-scarce and land-abundant countries. Even in large countries considered to have ample land, the population is very much more concentrated than usually believed: In Cameroon, for example, between 70 and 80 percent of the rural population is concentrated on only 20 percent of the land (see Figure 8). According to government estimates, over 80 percent of the land remains to be brought under cultivation. In land-scarce Kenya, the same proportion of the population is concentrated on even less land, just 10 to 15 percent of total area—but for very different reasons (see Figure 8). In the case of Cameroon, most people have tended to avoid the humid tropical rainforest areas (despite the higher agricultural incomes reported there from the production of cocoa, coffee, and oil palm) and farm in the milder climates; whereas in Kenya arable land forms such a small fraction of the total that the population is highly concentrated by necessity.

In fact, only in Kenya was there more or less a complete congruence between high population densities and high land potential, although as pointed out earlier people are now moving to more marginal areas. This congruence has profoundly affected the regional development of crop production. It has intensified regional specialization in food and cash crops, rather than promoting shifts into areas of lower density but good cropping possibilities. In Cameroon, Nigeria, Tanzania, and Senegal, the population has settled in the areas of highest "potential" or best cropping possibilities or lowest risk of disease, but large amounts of apparently fertile land remain with low population densities. In these latter countries and in the geographically smaller and climatically less diverse Malawi, the issue of population pressure on land has been framed largely as a "North-South" phenomenon; length of growing season and amount of rainfall are critical in determining the range of possible population movement. Especially in the West African countries, there is extreme population pressure in the drier northern reaches (between 500 and 800 millimeter isohyets) but an apparent gap of low density areas in the higher rainfall Sudano-Guinean zone to the South (e.g., the Casamance and Tambacounda regions of Senegal, the Middle Belt states of Nigeria, and the Adamaoua region of Cameroon). Not all the movement has been spontaneous, as the Boserup model would suggest: Governments have used a range of policy inputs to affect the movement onto these lower density lands, including producer prices, regional public investment, and the development of smallholder institutions. Before analyzing shifts in production, we first consider the regional distribution of population, land use, and land productivity by region.

Figure 8
Distribution of population on total land area

Population Densities in Relation to Quality of Land

"High potential" can be considered in terms of yield and response to fertilizers or in terms of income-producing capacity, such as the capacity to grow high value crops. The

two are not always synonymous. An analysis of the price effect on shifts in production is given in Lele (1988a) and will not be repeated here; we will focus exclusively on yield data insofar as they are available.

The substantial regional variation in population densities is not apparent in either the aggregate figures or the distribution curves. The degree of regional variation can be seen more clearly by looking at the annexes, which give the regional breakdown in population for each country by province or other geographical subunit. As mentioned earlier, the data on land quality and land use cannot be treated as authoritative in most cases. They are used here to give a rough idea of *how* population is distributed over *what* kind of land.

According to the FAO/UNFPA/IIASA study, Kenya faces the worst land constraint and has the greatest need for intensification. This observation is supported by the fact that population is heavily concentrated in the high productivity areas and, as we saw earlier (Figure 1), is migrating into more marginal areas. Roughly 65 percent of Kenya's population is concentrated on just 9 percent of the land, which constitutes three-quarters of all high potential (i.e., humid and subhumid zones) land. As a result, the amount of per capita arable land is lowest in the three provinces with the *greatest* proportions of high potential land: Western, Nyanza, and Central provinces (see Figure 9).[25] In fact, while constituting only 6 percent of the total area in Kenya, these three provinces support almost 50 percent of the total population.

Two points bear mentioning with respect to crops yields: first, yields in the high potential areas of Central province for tea, coffee, and maize are on the order of two to three times higher than in the drier parts of the country such as the Coast province and sections of the Eastern province. Second, yields have not improved significantly in the smallholder sector due to increased production on marginal areas (Lele and Meyers 1986). Table 7 indicates that the Central province has a clear advantage in the production of coffee and tea. Striking in the data is the difference in yield between smallholders and estates; estate yields for coffee approached 1 metric ton per hectare in 1981, whereas smallholder production lagged behind at an average of .53 metric ton per hectare (see also Lele and Agarwal 1989). Smallholder coffee yields were highest in the Central province, as were smallholder tea yields—generally 25 percent higher than in its closest competitor, the Nyanza province, for the period 1973 to 1981. Nonetheless, the tea subsector in Kenya is also remarkable for its consistently equitable high rates of growth. For all provinces, growth in production fluctuated less than 1.1 percent, between 11.8 percent in Central and 10.7 percent in Nyanza. Thus, while output shares and yields may differ significantly, growth in production was largely balanced over the 1973-82 period (see Annex 3). The Rift Valley and Western provinces have a distinct advantage in the production of staple foods, reflected in their superior yields in maize production.

In Cameroon, almost 50 *percent* of the population is concentrated in the fertile Western Highlands and the high rainfall western lowlands, which cover less than 20 percent of total area. Data from the 1984 Agricultural Census and the Bilan Diagnostic indicate that on the whole the intensity of land use (as measured in percentage of area planted and fallow) is below 35 percent, but as expected is most intense in the more densely populated areas such as the Western Highlands region (see Figure 10). Similarly, the proportion

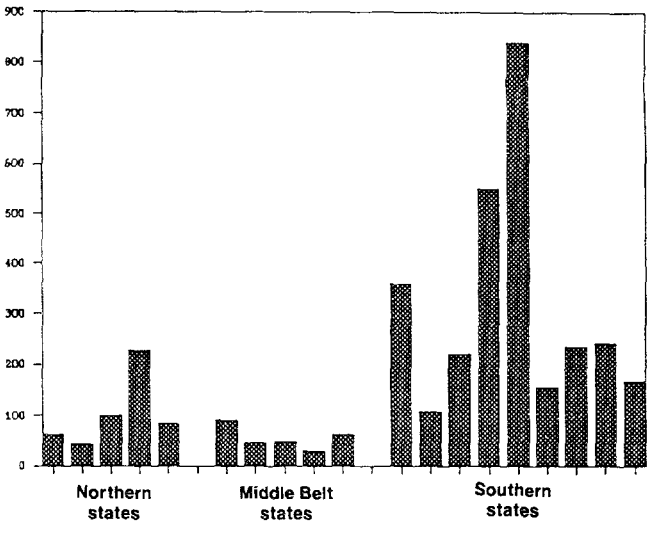
lying fallow appears to be lower in the higher density regions such as the Far North. The data should be taken as a rough approximation as they are derived from two different sources, but they indicate a correspondence between cultivated area and population densities. Furthermore, Table 8 indicates that yields of high value crops in these regions were generally higher than elsewhere in the country. Although the yield data are for a single year (1984, a dry year) and do not represent an average, they are still indicative of relative land productivity. One of the principal characteristics of Cameroon, in addition to its overall land abundance and relatively high concentration of population, is the use of parastatals to promote regional smallholder development (see Lele, van de Walle, and Gbetibouo 1989).

Soil surveys completed in 1986 also support the premise that the West and Northwest provinces show better potential than either the rainforest areas to the East or the savannah zones to the North (IFDC 1986). The large concentration of people in these high potential areas makes the provision of services and the creation and maintenance of roads and physical infrastructure relatively efficient, and consequently a smallholder-led strategy of intensification a realistic and cost-effective way to raise rural incomes. Investments in these areas, especially for transport capacity and human capital, are likely to have strong multiplier effects throughout the economy, not unlike those envisioned by Boserup as occurring spontaneously.

The lack of accurate data in Nigeria on either land, population or crop yields makes an accurate assessment difficult, but it appears that almost 50 percent of the population is concentrated in the *southern rainforest area.* Population densities in the southern states are as high as those found in the East African highlands (see Figure 11). Before the oil boom, this area—which covers just under 20 percent of the total area—earned a high agricultural income from the cocoa and oil palm tree crops. Since then, an overvalued exchange rate, a shift in terms of trade toward food crops, and unstable marketing institutions have undermined the returns from growing these crops, and

Figure 11
Population densities in Nigeria by region, 1986



Source: Lele, Oyejide, et al. 1989.

Nigeria has lost its former position as a supplier on the world market. Given intense population pressure in the South, which has from 200 to 500 persons per square kilometer, the government is moving to develop its less densely settled areas. Since the oil boom and Sahelian drought of 1973, two important policy instruments used to promote its objective of increasing food production have been fertilizer subsidies and the construction of large-scale irrigation schemes in the Northern region (Lele, Oyejide, et al. 1989). Those familiar with Nigeria expect that the greatest room left for area expansion is in the lower density Middle Belt states with an estimated 53 persons per square

kilometer. As pointed out earlier, densities are lower here than in the North for reasons of health, a factor contributing to labor shortages in the Middle Belt. The government's emphasis on promoting regional food crop specialization and mechanization in the Middle Belt is underscored by the recent import ban on grains and extension efforts in the North using the World Bank-sponsored agricultural development projects (ADPs).

In Tanzania, a land-abundant country, as much as 60 percent of the population lives on 20 percent of the land. Population in this case is concentrated around the Lake Victoria Basin (26 percent of the total) and the coffee producing Northeastern Highlands (11 percent), areas of traditionally higher value and higher-yielding crops. Both these regions have a history of intensive land use, including irrigation, but the farming techniques that have evolved there have to date not been complemented by public policy to intensify production. Smallholders, for instance, receive only one-third to one-half of the world price for dark-fired and sun/air-cured tobacco (see Lele 1988a). Concerned about population pressure, the government has tried to open up new areas of high potential in the Southern Highlands. This strategy makes sense in the long term, but in the short run it has high opportunity costs in terms of returns foregone that would occur more immediately in the more accessible Northeastern Highlands. The fiscal problems encountered by Tanzania illustrate the dilemma of giving regional equity a higher national priority than growth in overall production.

In Senegal, there appears to be even less congruence between population and land potential. It may be that historical and health-related factors have militated against the movement into high response areas. The purposeful concentration of infrastructure—roads, schools, railways—in the Groundnut Basin of Senegal, and subsequent settlement by Wolof "visionaries" may, for instance, help to explain why its densities are higher than in the regions to the South. If the data are reliable, Figure 12 shows that in the most densely populated areas (those in the Groundnut Basin) farmers are reaching the limit of the area frontier. Data presented in Table 9 suggest that crop yields for groundnuts and sorghum/millet are on average as much as two times higher in Casamance than in the rest of Senegal but that average population densities there are substantially below those found in the Groundnut Basin: 14 as compared to 45 persons per square kilometer. Almost half of the total population lives in the Groundnut Basin. In fact,

the majority of the Senegalese—72 percent, including the population of Dakar—live in the drier Sahelo-Sudanian zone (350-600 millimeters per annum). Rainfall is likely to become more of an issue insofar as it has declined significantly over the past two decades. The relatively better performance for Casamance and its more favorable placement in the Sudano-Guinean zone suggest greater production possibilities for groundnuts as well as other crops; according to government estimates, over two-thirds of the arable land in Casamance remains to be brought under cultivation.

Finally, the population in Malawi is largely concentrated in the Southern region—a full 49 percent of the total. Of the 5.3 million hectares classified as cultivable in the most recent land survey, 42 percent is already under cultivation.[26] The extent of land use, expressed as the proportion of cultivable land that is already cultivated, is highest in the crowded Blantyre agricultural development district at over 60 percent, followed by Lilongwe and Kasungu ADDs, with just below 60 and 50 percent, respectively (see Figure 13). These figures *do not* include land held fallow; they are merely the crop estimates for total area. Were they to include land held fallow it is likely they would approach 100 percent of cultivable land. In fact, if one uses the more conservative estimate of only 22 percent arable (without forests), over 100 percent of available land would already be under cultivation.

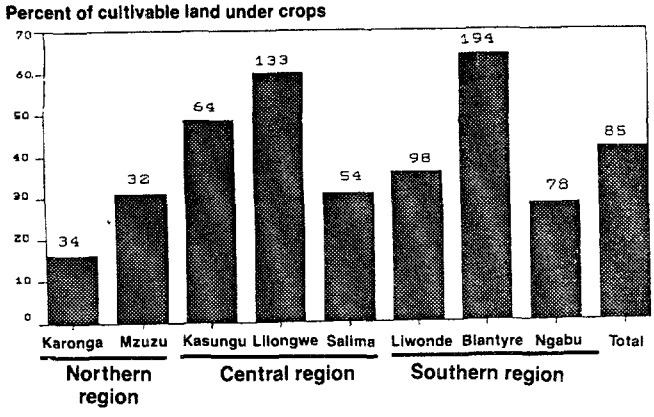
Figure 13
Intensity of land use and population densities in Malawi by region



Source: National Statistical Office 1977; 1988.

A probable cause for the high concentrations in southern Malawi is the location of the former capital of Blantyre; although the capital has moved since independence to Lilongwe in the Central region, the area around the former capital—Blantyre ADD—still contains over one-quarter of Malawi's population. The problem is complicated by refugee movement onto the land from neighboring Mozambique. Contrary to what one might expect in the Boserup model, the yield data presented in Table 10 suggests higher yields in the Central region for maize, groundnuts, and tobacco, apparently unrelated to population densities.

Two other important features in Malawi bear mentioning; first, Table 10 indicates much higher yields for estate-grown tobacco, generally twice as high as those found in the smallholder sector. Lele and Agarwal (1989) document that the lower yields for smallholders reflect their lack of access to inputs and better performing burley and flue-cured varieties. It is estimated that more than 80 percent of estate tobacco area is underutilized (Deloitte, Haskins, and Sells 1986). The second salient feature of land use in Malawi is the apparent decline in yields over time: In the most intensely cropped areas like Lilongwe, a decline in soil fertility has reduced response coefficients for fertilizer on hybrid maize from 23 to 13 between 1957-62 and 1982-84 (Twyford 1988). This observation squares well with recent data from FAO showing that, in general, for each 4,000 kilograms per hectare crop of maize, 200 kilograms of nitrogen, 80 kilograms of phosphate, and 160 kilograms of potassium are removed from the soil (Higgins). Others argue that soils either have or do not have the major plant food elements, which if they are there are not easily exhausted by cropping. If not there they must be added. Nitrogen is an exception as it is generally very quickly exhausted. The drain on soil nutrients caused by continuous cultivation and reduction in fallow periods underscores the need for more resourceful cropping patterns, such as including leguminous, nitrogen-fixing shrubs in the plot. Also, changing the structure of output to higher-yielding and higher value crops—both a function of policy—will by producing higher incomes alleviate the pressure brought to bear by increasing population.

The main thrust of this section has been to point out the production possibilities of the various regions where populations are concentrated, and what the implication is for a policy-led approach to intensification. In countries where population is highly concentrated on the most productive lands, investment choices are easier from an economic standpoint: The marginal cost per head of extending smallholder services, such as credit, marketing channels, and inputs are small given the potential returns. Elsewhere, investments in infrastructure and social services are more costly but may be required to attract population to underutilized land. The Casamance region in Senegal or the Southern Highlands in Tanzania are cases in point.

A final note before closing this section: Investment decisions must be extremely sensitive to the social constraints to migration, such as ethnicity. Latent antagonisms may rise to the surface with migration. The long-standing antipathy between the Wolof, for example, who dominate the Groundnut Basin, and the Diola, a non-Muslim group inhabiting the lower Casamance, is likely to complicate migration in Senegal. One observer notes that:

> if the relatively well-watered Casamance is to become an agricultural growth area for Senegal, the Diola will have to be given a greater share of national resources and be represented in the elite...if "development" comes in the attache cases of northern technocrats, the unhappy story of the Southern Sudan or even of East Pakistan may well be repeated (Waterbury 1989).

Similarly, ethnic tensions between the Hausa of the North and Yoruba and Ibo of the South may interfere with planned development to induce migration into the lower density Middle Belt states. Interregional migration has reportedly more or less stopped since the civil war, but even before that, migration to the Middle Belt from adjacent areas in the North and South appears to have been largely confined to homogeneous ethnic groups (Lele, Oyejide, et al. 1989).

Population Densities and Incomes

Integrally related to the "potential" of the land is the income that derives from agricultural production. In terms of income, land potential is determined by such variables as the length of growing season and quality of soil (i.e., the standard agronomic definition), as well as by access to land and secure land tenure, legal right to grow high value crops, extension, input and output marketing services, and the degree of implicit or explicit taxation of crops. As the level and quality of these services in developing countries are largely tied to government initiative to provide them, income potential by region is as much a function of policy as it is of regional resource endowments. The interaction of smallholders and government changes the simple dynamic outlined in Boserup's model, especially when land becomes scarce throughout a country. The evidence uncovered from the MADIA sample suggests that income levels do not always follow population densities, in either land-abundant or land-scarce countries.

The point can be illustrated by taking two extremes. In Cameroon, for instance, it is estimated that 80 percent of its arable land remains to be brought under cultivation. Given appropriate cultivation techniques (retaining vegetative cover), it has a wide margin for area expansion. The highest agricultural income-earning areas in Cameroon were those areas *least densely populated* (see Figure 14); the high density areas received lower incomes, based more on the sale of food crops than of what are traditionally termed cash crops (see Figure 15). These findings relate back to the definition of *high potential* land that looks more at income and therefore uses value of crops grown to measure land potential, as opposed to FAO definitions that classify potential simply in terms of soil quality and rainfall patterns. The data suggest that people chose to forgo the better income opportunities of the tropical rainforest areas and instead are concentrated in regions of more moderate climate.

In Senegal, by way of contrast, populations are concentrated in the high income areas. The production of groundnuts, Senegal's principal export crop, is concentrated in the high density Groundnut Basin. Four-fifths of total groundnut production accrues to the regions in the Groundnut Basin, and close to 50 percent is produced in the Sine-Saloum (Kaolack and Fatick) region alone (see Annex 3). The latest available data from 1975 suggest that almost one-third of total crop income, or 22 billion CFA, accrued to the Sine-Saloum (see Table 11). The higher density Groundnut Basin, with 49 percent of total population, received 58 percent of total rural income in 1975, with well over two-thirds of its total income derived from crops. Waterbury (1987) argues that the Groundnut Basin also had preferential treatment in institutional arrangements in the colonial era for marketing groundnuts and in some years received substantially more than the world price. The lack of more recent data on income makes it hard to assess what has happened in more recent years, especially in light of erratic and declining rainfall and soil erosion. But it is evident that development of the Basin is no more the priority it once was. Lele, Christiansen, and Kadiresan (1989) have documented that fertilizer consumption has virtually collapsed in the Groundnut Basin, and that investment has shifted to irrigated rice production in the Fleuve region.

These two cases contradict a commonsense interpretation of the Boserup hypothesis: One would expect, all things being equal, that the acute demand for productive land in Senegal would force people into the Casamance area to exploit its apparent higher yields in crop production. However, variables other than population density appear to be affecting the natural processes of autonomous intensification (here, area expansion) observed elsewhere by Boserup. These variables include social and ethnic factors, the choice of crops grown, the prices received for those crops, and public expenditure. Even though one region may be densely settled—for reasons of better infrastructure, social services, or climate—it does not axiomatically lead to higher incomes. Incomes also depend on the congruence between land potential and adequate labor to produce high value crops. Incomes are higher in the low density areas of Cameroon, for example, because the crops grown there, cocoa and oil palm, fetch a premium

on the world market, and even though the government of Cameroon taxes cocoa production heavily, farmers still receive a healthy margin. This would be impossible under the production of low value crops.

Just as in land-abundant Cameroon, incomes in land-scarce Malawi are highest per household in regions of *lowest population density* (see Figure 16). Kasungu, Ngabu, and Karonga are the lowest density ADDs (57, 54, and 34 persons per square kilometer, compared to the national average of 76) but they have the highest average household incomes, at 213, 143, and 142 kwacha a year, respectively (about US$70-100). In the high density areas, land is so short that small farmers have difficulty earning an adequate income from crop production. Despite the greater role of agriculture in the Malawian economy, crops contribute only 34 percent to total rural household income. The dominant source of income for smallholders is business or trading, at 27 percent of the total; the second largest source of cash income is *food crops*, at 23 percent of the total. Cash crops—generally higher value crops typically grown for export—contribute only 11 percent on a national average to smallholder incomes (see Figure 17). The data indicate that where crops have contributed significantly to total household incomes, the absolute level of income is higher. The observation is consistent with the literature on Asia that emphasizes the importance of agriculturally-led growth (Mellor and Johnston 1984). Were the government to allow or encourage the production of higher value crops, it could potentially alleviate the land constraint by raising the incomes of smallholders.

In Kenya and Tanzania, high incomes were found in areas of high population density, but lack of recent data makes it difficult in the case of Tanzania to assess the income effects of shifts in production to the Southern Highlands. For Kenya, a high correspondence between population densities and good land quality means that incomes have tended to be higher and remain localized in the areas growing high value crops. Table 12 indicates that the 1974-75 survey, the last to include income data, shows that over half of the households surveyed in the Central and Rift Valley provinces of Kenya earned more than 3,000 Kenya shillings. Likewise, the mean value of farm assets for the two provinces was substantially above those found in other provinces. The Nyanza, Eastern, and Coast provinces had

lower proportions of households above the 3,000 Kenya shilling mark, and the Western province had the lowest—70 percent below the 3,000 Kenya shilling line. Remarkably, only the Rift Valley had a higher proportion of households earning no cash income than did the Central province, at 16 versus 10 percent, indicating a concentration of subsistence farmers in the two most well-to-do provinces. The apparent distribution problems in these two provinces point to the need for more accurate and up-to-date information to assess the effects of rapid growth in high potential areas.

Although data on regional income are even more limited in Tanzania, it appears that the traditionally most densely populated districts (Kilimanjaro, Mwanza) also received the highest incomes. However, owing to shifts in production from North to South, the picture may have changed. In former times the coffee-producing Kilimanjaro region had the second-highest regional GDP (1970), after Dar es Salaam (see Annex 2). More recent data on regional incomes are not available, making it difficult to distinguish whether incomes still follow population densities as they do in Kenya. Other piecemeal data on fertilizer consumption, investment in roads, and marketed surpluses of tobacco, tea, coffee, and maize suggest a clear shift away from the northeastern and Lake Victoria areas toward the South.

The specialization in high-value crops by certain regions such as the Central province or Northeast Highlands raises interesting questions about regional comparative advantage. In the next section we examine the shifts in production in the most important crops, treating the shifts as outcomes to autonomous changes arising from localized population pressure (autonomous intensification); supply response to price changes; supply response to regional investment patterns, and supply response to other non-price factors such as institution-building at the regional level.

Population Densities and Regional Crop Production

Data on regional crop production over time—insofar as they are available—indicate a shift in production among regions, generally away from high density areas, and apparently owing more to policy initiatives than to spontaneous migration. Only in Kenya was there no perceivable shift in marketed production, a fact attributable to the apparent congruence between population concentrations and cropping potential of the land. In Tanzania, as mentioned above, government investment policy encouraged production in the low density Southern Highlands. In Senegal, investments in irrigation in the Fleuve region have caused rice production to shift to the North and away from Casamance. Reliable time-series data for Nigeria, Cameroon, and Malawi are not available, but there too it appears that production has shifted into lower density regions. The spontaneous movement into new areas sits well with the Boserup model, but as the following sections try to demonstrate, the picture is somewhat more complicated.

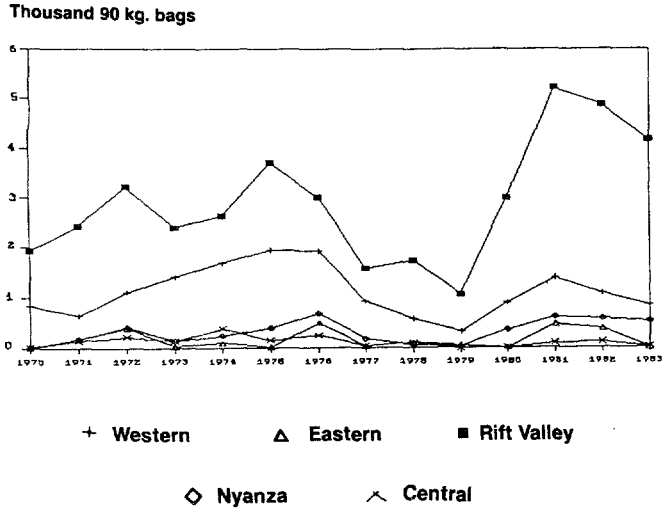
Food crops

We begin by looking at maize in East Africa, because it is marketed and records of official purchases are readily available. While there is a good deal of informal marketing, official sales nevertheless provide some important insights. In Kenya, for example, maize is produced throughout the country but in largest quantities in the Rift Valley. Between 1970 and 1985, 38 percent of maize production on average came from Rift Valley, from 27 percent of the area under cultivation (see Annex 4). The Eastern province, which grew by 1 percent in production and 4 percent in area, registered a 26 percent share of total area on the average, but produced only 13 percent of total output. The lower returns on the increased area in Eastern province may indicate an expansion onto marginal lands.

Furthermore, the Rift Valley sold the highest percentage of maize to the National Cereals and Produce Board (NCPB) with 63 percent on average, followed by Western province with a 24 percent share (see Figure 18). These figures are substantially higher than those given above for total output, where the Rift Valley had a 38 percent share of production. This suggests that a large part of the Rift Valley and Western maize output is channeled through the NCPB, whereas for other provinces, such as Eastern and Central, output bypassed the parastatal and was consumed locally. Central and Eastern provinces, for example, produced 13 percent and 12 percent of total output for maize, but accounted for only 3.4 percent and 2.5 percent, respectively, of maize sold to the NCPB for the 1970-84 period. Percentage amounts of maize *purchased for consumption* are shown in Figure 19, and confirm this observation; they indicate that households in Eastern and Central provinces purchase over 40 percent of their grain (for their own consumption) on the market. What Figure 19 cannot show is the extreme fluctuation in regional market dependence, especially in drought-prone or marginal areas.

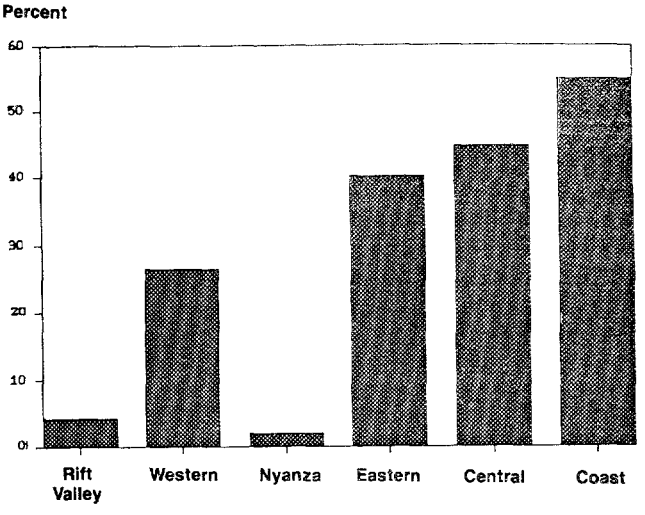
The problem of market dependence is complicated by

Figure 18
Official maize purchases in Kenya by region, 1970-83



Source: NCPB 1985.

Figure 19
Maize purchases for own consumption in Kenya

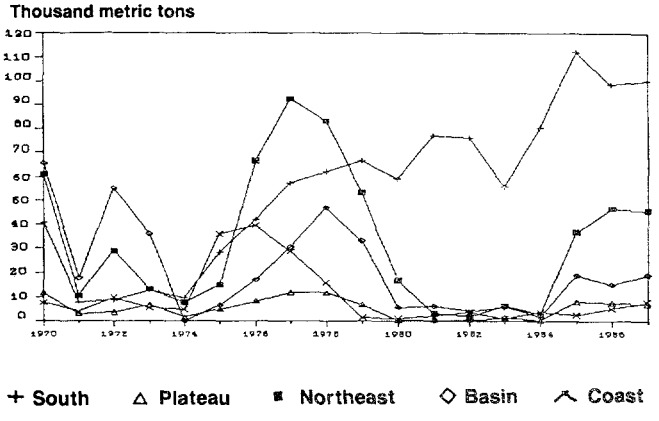


Source: Government of Kenya 1983.

projected decreases in per capita arable land. Little agricultural land is available per person in these areas already, and Table 13 shows that in most cases those amounts will fall by up to 40 percent by the year 2000. As population grows, more of the land will be allocated to maize production. Table 14 indicates that projected maize deficits will grow in many districts and that many districts formerly showing a surplus will record a deficit. Especially in the more marginal districts, the difference between a good year and a bad one can have serious implications; based on the projections in Table 14 four out of the six districts in Eastern province would slip from maize self-sufficiency to a deficit in maize without a "good" harvest. The rapid population growth and shrinking per capita land supply emphasize the need for policy-led intensification, especially in countries such as Kenya where little remains of the area frontier. The MADIA paper on fertilizer explores the implications for input use in high and low potential areas for both growth and equity; another explores the implications for food policy (Lele, Christiansen, et al. 1989).

In the case of Tanzania, as a result of policies such as pan-territorial pricing that discriminated against the Northeast Highlands, the production of marketed maize shifted over time from the Northeast Highlands and Dodoma province to the Southern Highlands. In 1970, the Kilimanjaro, Arusha, and Dodoma provinces accounted for over 64 percent of National Milling Corporation (NMC) purchases; by 1987 that figure had dropped to less than one-third. Regions in the Southern Highlands, by contrast, rose from about 22 percent in 1970 to over 55 percent in 1987 (see Figure 20). The shift in marketed production is away from the relatively high density regions to the North to lower density highlands in the South. For the 1978-87 period, for which data are available, between 40 and 60 percent of the officially marketed surplus was sold in the Coast region, including Dar es Salaam (see Annex 2). Even though the high potential Northeast Highlands have stopped selling surplus maize to the NMC, it appears they are roughly self-sufficient and—with the notable exception of Dodoma—have not increased purchases of officially marketed maize.

Figure 20
Official maize purchases in Tanzania by region, 1970-87



Source: Government of Tanzania 1980; 1987.

Given the high population densities in the northeast, there is an urgent need for intensification of high value crops.

In Malawi, yield differences across regions are not so large (see Table 4) as to confer a regional advantage in maize production. Nevertheless, because of extreme population densities in the South, regional surpluses have shifted over time, and two trends stand out. The Central region emerged in 1974 to become the leading supplier of maize (see Figure 21). Concurrently, the limited data for sales show an increasing dependency on the market in the Southern region, where population pressure is most intense. Between 1983 and 1986, the Southern region accounted for one-half to three-quarters of total maize sales from the Agricultural Development and Marketing Corporation (ADMARC) to smallholders. As referred to earlier, Twyford documents the decline in response to fertilizers in this region as it has been most intensively cropped, which could signal mining of the soils and perpetuate the circle of

Note: For maize balance 15% deducted for fodder and losses. Assumes 2.5% overall yield growth distributed in accordance with districts' growth potential. Area growth 1% in Central, Nyanza, and Western provinces, otherwise 2%.

Some have expressed doubts about the district maize balance results in this table. For instance, G. Stern observes, "...Machakos production fluctuates between feast and famine depending on the weather, but it is hard to believe that in a favorable year, by 2000 its surplus would be second in the country and very close to first.... Kakamega data [are also] surprising. At one time, the district (called North Nyanza) included Busia and Bungoma, and it was Bungoma that generated major surpluses.... [it is] hard to believe that Kakamega with some of the most densely populated areas could generate sizeable surpluses. One can divide the district into the heavily populated South that will be as or more food deficient than Kiambru district; a reasonably self-sufficient, fairly heavily populated center and a potential surplus, less densely populated North. The surpluses in the North could not do more than meet the deficit of the South" (Personal communication with the authors).

lower crop yields and greater market dependence.

Data for West Africa are more scarce, making it hard to point to areas of food surplus or deficit. In Senegal, for instance, it appears that the country as a whole is shifting into sorghum and millet. Its share of total cultivated area grew from 42 percent in 1963 to 53 percent in 1987. Jammeh and Lele (1988) argue that the shift into millet and sorghum reflects an attempt to manage climatic uncertainties and reduce risk. The most dramatic increase in area and production occurred in the densely populated Groundnut Basin, particularly in the Sine-Saloum (Kaolack and Fatick) region, where between 1961 and 1976 area and production doubled, from 157,000 metric tons to 322,000 metric tons, dropping slightly in 1987 to 290,000 metric tons (see Annex 3). The problem of area expansion in this high density region is compounded as we saw earlier by the fact that, according to government estimates, little arable land remains to be brought under cultivation in these regions (refer to Figure 22). Area and production of sorghum and millet rose much less in the lower density Casamance region, which instead showed a steady increase in maize production and variable performance in rice production. Rice production increased in the irrigated northern Fleuve region. The lack of data on officially marketed production makes it difficult to pinpoint food surplus areas, but from production data it appears that the shift in food crops has consisted mainly of a diversification in the better watered regions to the South and more rice production in the North. While this is a desirable move in principle, the remoteness of these regions and their very small populations make improvements in employment and income generation less effective than would be the case if the Groundnut Basin were the focus of development.

In Cameroon, information on marketed production is available from survey data only for 1984, which was a drought year. The Northwestern Highlands accounted for over half the marketed maize (100,000 metric tons), just under a third (122,000 metric tons) of the plantain, and about one-quarter of marketed cassava (85,000 metric tons), making it a food-surplus region despite its high densities (see Annex 1). Gaviria (1988) points out that the major food flows are from the West province, while the primary destination is the Littoral province. As we saw earlier, the proportion of income deriving from food crops was highest in the Northwest and West provinces, at 79 and 57 percent of the total, respectively.

Nonfood crops

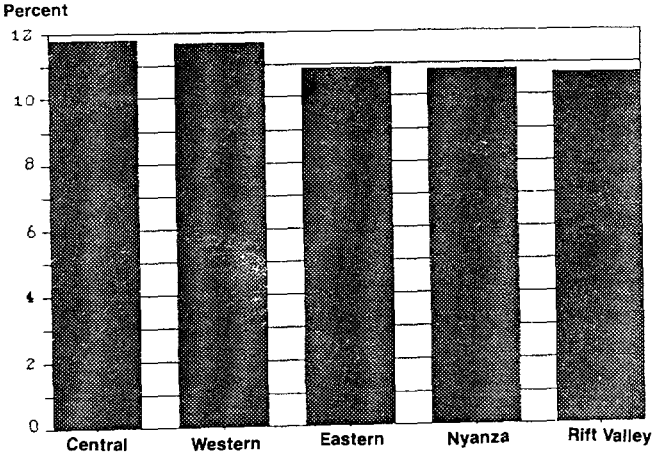
Shifts in the production of high value export crops among regions were most significant in Nigeria, Tanzania, Malawi, and to a lesser extent Cameroon. In all four cases, the shift away from the traditional centers of export production resulted from explicit policy objectives, not from spontaneous or autonomous migration as might be thought under the Boserup paradigm. Although it is common sense that policy will figure largely in the structure and location of

agricultural production, it is important to underline this point to dispel the belief that a *laissez-faire* approach to population growth, by allowing market forces to operate, will correct for factor scarcities.

In East Africa, two points emerge: Production shifted into low density areas in Tanzania and Malawi, and production concentrated in the high potential regions of Kenya. In the case of Tanzania, as pointed out above, the government encouraged a shift in production away from the Northeastern Highlands to the Southern Highlands. Although total production of coffee grew at only 2.3 percent and tobacco at -4.8 percent, the relatively low density Southern Highlands doubled its share of total coffee production to 25 percent in 1981-85, and increased its share of tobacco production from 18 percent in 1970-74 to 60 percent in 1982-86 (see Annex 2). The redistribution in production was not associated with substantial growth in overall output, due to a decline in traditional areas.

In Kenya, the data indicate little change in relative shares of cash crop production. For the period 1973 to 1981, for instance, the Central province dominated, accounting for half of all tea production. A striking feature of tea production in Kenya is that it grew evenly among the provinces, generally above 10 percent a year (see Figure 23). In view of the country's very tight land constraints, the story of tea development there is a model of policy-led intensification. Data on coffee production, while more limited, again point to a concentration in the Central province, where growing conditions are the best, and to a lesser extent the Eastern province (see Annex 5).

Figure 23
Growth in tea production in Kenya by region, 1973-82



Source: KTDA Annual Reports.

In Malawi, it is striking that the government policy favoring estate agriculture led to the dramatic expansion of such production throughout the country, even in the high density Central and Southern regions. One consequence of estate agriculture in areas of tight land supplies was to increase environmental stress on land under smallholders (see Lele and Agarwal 1989).

In West Africa, a series of price, investment, and institutional policies affected the regional production of export crops. Especially in Nigeria, traditional export crops in the South declined as oil revenues supplemented them. The effects of this shift away from the South and on the economy as a whole are documented in Lele, Oyejide, et al. (1989). In Cameroon, no time series data are available, but important gains in cotton and rice production in the North are documented by Lele, van de Walle, and Gbetibouo (1989). These authors point out how parastatals played a vital role (SODECOTON, SEMRY) in encouraging this regional shift. The allocation of resources to develop the dry northern area raises questions about optimal efficiency that must be reconciled with the government's agenda of equitable development as a nation. Similarly in Senegal, large investments in the North do not provide the government with the highest economic return but may meet other politically important criteria. It is to a brief analysis of expenditures that we now turn.

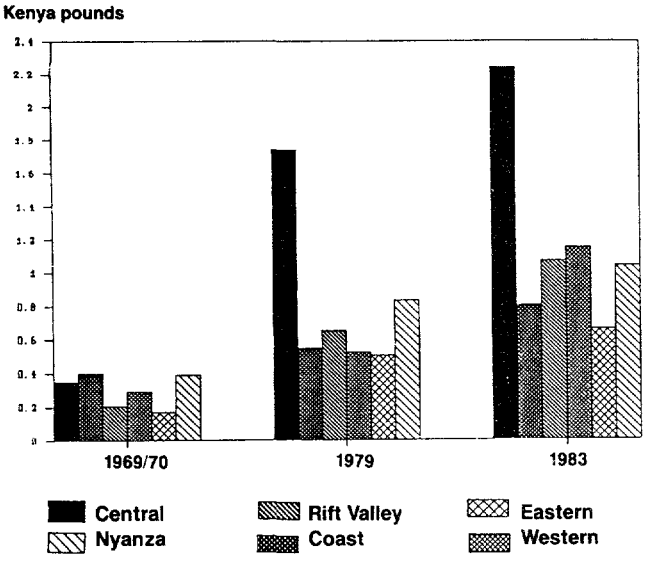
Population Densities and Regional Public Expenditures

Data on regional public expenditures must be treated with caution, as there is no preexisting methodology to calculate rates of return, nor are there enough adequate or reliable data on which to base such an analysis. However, it is possible to make some tentative observations based on the limited data available. The most important point to emerge is that, beyond the simple mechanics of increasing population densities, regional and sectoral allocations by governments will shape the pace, direction, and location of intensification.

The point can be simply illustrated by considering expenditure patterns in Kenya and Tanzania. Both countries inherited fertile highlands endowed with an indigenous labor supply. Yet their responses were almost exactly opposite. Kenya chose to develop its high potential areas explicitly (some would say was compelled out of political expediency) whereas Tanzania shifted expenditures in favor of its high potential but less developed, less populated regions.

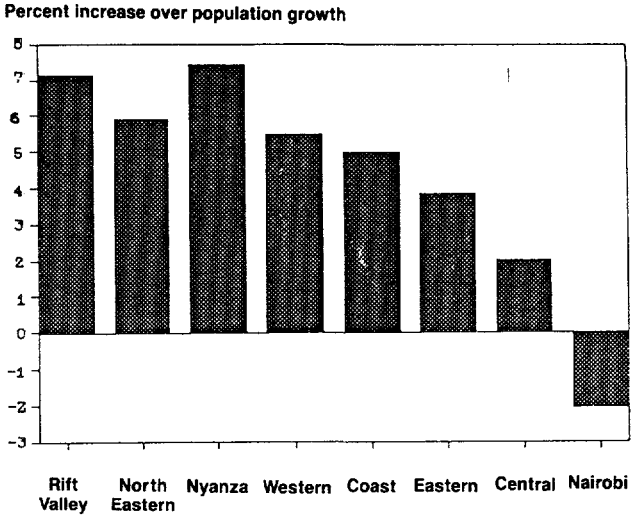
In Kenya, for instance, expenditures on main services between 1970 and 1983 grew fastest in the high income, high potential Central province, at 6.2 percent in real terms. In the second half of this period, subsequent to the death of President Jomo Kenyatta in 1978, the Central province received consistently up to one-third of regional expenditures; similarly, per capita expenditures were substantially above those in other provinces (see Figure 24). It was followed by the Western province, where expenditures grew by 4.9 percent in real terms, compared to the national average of 2.4 percent real growth. The provinces exhibiting the fastest growth in expenditure also showed the greatest degree of ethnic homogeneity: The Kikuyu dominated the Central province, composing 95 percent of its population in 1979, as did the Luhya, with 86 percent, in the Western province, with both groups exceeding 1.5 million persons. The data suggest that rather than trying to reduce regional income disparities, as was the case in Tanzania, the government used its expenditures to reward its most vocal, active, and vital constituents. In the process, the government spent more to develop high potential areas than it did on other provinces, a policy that paid off in high rates of growth. Significantly, growth rates for primary school enrollment for the 1968-84 period show that, despite higher spending in the Central province, other provinces benefited from more rapid growth in jobs and education (see Figure 25; see also Annex 4).

Figure 24
Per capita regional expenditure in Kenya by region, 1969, 1979, and 1983



Source: Kenya Statistical Abstracts.

Figure 25
Growth in primary school attendance in Kenya by region, 1968-84



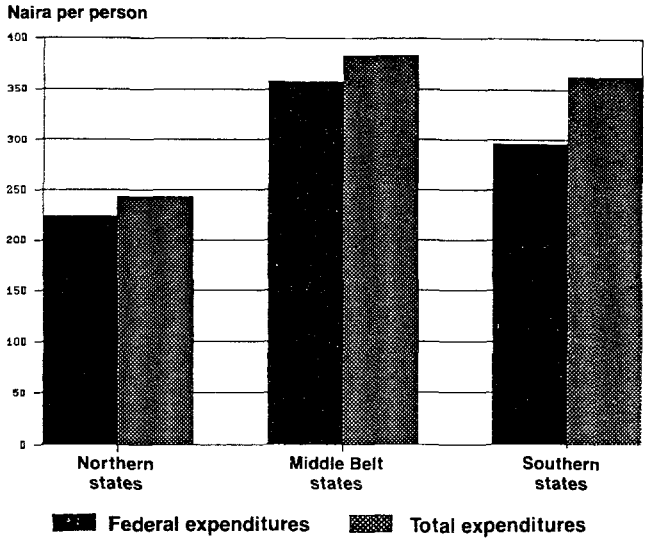
Source: Kenya Statistical Abstracts.

In Tanzania the government adopted a totally different approach: Rather than try to develop the high density, high income areas, as was the case in Kenya, it used regional expenditures to try and narrow regional income disparities. This was politically feasible because no one particular ethnic group dominates in Tanzania. Total expenditures were lowest in the high potential Northeast Highlands, at roughly 12 percent of total for the period, while a greater share (in both absolute and per capita terms went to the lower potential coastal belt which received 25 percent, and the central and western plateau, which got 20 percent) (see Annex 2). Tanzania's regional redistribution problem was complicated by changes in intersectoral patterns. Government expenditures on the directly productive agricultural sector declined, while increasing on social services, especially education. For Tanzania, the emphasis on equity and provision of social services to the exclusion of growth caused many problems. Chief among them was the inability to finance recurrent expenditures (Tanzania Agricultural Sector Report 1983). Total expenditures rose rapidly until they peaked at 3.4 billion Tanzania shillings in 1983, before falling to one-third of that level in 1984. Further, expenditures on transportation declined, aggravating the already poor mobility of labor and goods in Tanzania. Whether redistributing national income on equity grounds is a prudent approach toward intensification is debatable. This paper argues that when resources are scarce, the most productive investments are in areas with the highest returns.

We close this section on regional expenditures by citing the cases of Senegal and Nigeria where neither the Kenyan nor the Tanzanian pattern is repeated. Senegal chose to invest a slightly higher proportional share in the outlying (i.e., non Groundnut Basin) areas. In fact, although almost half of the population is concentrated in the Basin, only 28 and 14 percent, respectively, of total investment went to this area in the Fifth and Sixth Plans (1977-84, see Table 14). In both absolute and relative terms, more money was directed to the outlying regions. Significantly, the drier Fleuve region in the North of Senegal received as much investment as the Casamance region in the Fifth Plan, at 11.5 percent each, and slightly *more* in the Sixth Plan, at 10.0 compared with 9.7 percent, despite the fact that Casamance has a greater share of the total population (14 compared to 9 percent), higher population densities, and according to the latest land statistics four times more "unused but potentially cultivable" area. In fact, investments in the Fleuve area (mostly in irrigation) fell less than in any other region in the Sixth Plan, indicating the government's commitment to (or inability to withdraw from) costly investments already made. One might be led to conjecture that investments in the Fleuve region have a good deal to do with local and ethnic allegiances: The largest proportion of "fonctionnaires" in the government, roughly one-fifth, were born in the Fleuve region (*Le Senegal en Chiffres* 1982/83). Our judgment is that investments in Casamance, a low density/higher rainfall region, will pay off more quickly and do more to ease population pressure in the Groundnut Basin.

Finally, capital expenditures in the agricultural sector in Nigeria have shifted since the early 1970s from the highest density Southern regions to the relatively less dense North. In 1981-1985, for instance, less than 10 percent of the regional budget, or 1.3 billion naira, was allocated to investment in agriculture in the Southern states, whereas the figure for the Northern states (thought to be more economically depressed yet politically quite important) is higher, at 1.5 billion naira, and accounts for a larger share of its regional budget, at 18 percent. The expenditures in the North increased in 1981-85 because of the statewide agricultural development projects in Sokoto, Kano, Bauchi, and Kaduna. On a per capita basis, however, the Middle Belt states came out favorably, given its lower population (see Figure 26). Another tack pursued by the federal

Figure 26
Per capita government expenditures in Nigeria by region, 1981-85



Source: Lele, Oyejide, et al. 1989.

government was to subsidize fertilizer sales, two-thirds of which were consumed in the North. The salient point is that public policy plays a crucial role in the intensification process, and that regional expenditures are an effective way of guiding the autonomous forces that arise out of population growth.

Population Densities and Input Use

One of the main tenets of the Boserup hypothesis holds that the incentive to use more inputs (land, labor, and capital) grows in proportion to population densities. The most common and readily available input is labor; it is estimated that on average, up to 80 percent of value added in Africa's agriculture comes from labor. In this section we therefore survey available evidence on labor use by region before turning to examine the use of other inputs such as farm implements, seeds, and fertilizer that can increase the productivity of land and labor. Three findings are significant: First, on-farm labor use increased commensurately with higher densities, especially in areas that tended to specialize in export crops or food crops for the market; second, the use of hired labor is correspondingly higher in high income areas; and third, data on consumption of fertilizer and improved seed indicate that the model of increasing input use with higher densities is at best only partially true, even for the most land-scarce countries; government priority for promoting fertilizer use has been determined by other priorities (Lele, Christiansen, and Kadiresan 1989). In Kenya improved seed adoption has increased to 60 percent, but fertilizer use on small farms is apparently growing less impressively. The reverse is true for Malawi, suggesting the absence of a well coordinated strategy emphasizing the complementarity of inputs. The evidence supports the contention that at early stages of development, national and regional policy initiatives will be of critical importance in adopting inputs to improve factor productivity.

The cases of Cameroon and Malawi, both of which have excellent and up-to-date rural survey data compared with the other MADIA countries, set a striking contrast in patterns of labor use. In Cameroon, the fact that land is still abundant is reflected in the low proportion of hired labor in the agricultural labor force, just under 2 percent in 1984. Significantly, the highest proportion of hired labor in agriculture (roughly 6 percent) obtained in the high income Southwest province (see Table 15). This province alone produced one-third of the total cocoa (35,000 metric tons) and one-fifth of the oil palm production (17,000 liters), earning over one-fifth of the country's total cash crop income in 1985. A strong correlation between high income and high hired labor input would seem to be borne out, regardless of population densities: The Southwest province had one of the lowest densities in lower Cameroon, at 33 persons per square kilometer. The absolute amount of labor per farm is highest, by contrast, in the higher density Northwestern Highlands, at roughly 4.5 workers per farm, compared with the national average of 3.7. Hired labor is higher where cash crops are grown, but total labor input corresponds more to population densities.

The case of Malawi presents an extreme contrast. According to the 1980-81 rural survey, 55 percent of all households cultivate less than one hectare of land. Even more striking, those 55 percent account for a meager 25 percent of the total area cultivated (see Table 16). Lele and Agarwal (1989) document the implications of land distribution and shrinking plot size, including the effects on intensification. In the Southern region, population densities reach 200 to 300 persons per square kilometer. There is a growing number of individuals selling their labor to earn an income; the Southern region accounts for over half of the number of people earning wages through agricultural work (see Figure 27). Plot size has become so small that the "normal path" of intensification is bypassing Malawi. The negative effects of Malawi's emphais on growth is a sobering counterpart to the extreme emphasis on equity in Tanzania.

That the traditional path of moving to higher levels of production has not been achieved is also shown by the means of cultivation used in Malawi. In the most densely populated regions, over 90 percent of the land is cultivated by hand (see Annex 5). Oxen are used more extensively, in the lower density Northern regions, where almost one-third of the total area is cultivated using draft animals. This option is precluded in the Southern region as no land is available for growing fodder. The prevalence of hand tools in Cameroon, used by 85 percent of the farming population, is less of a handicap to land productivity given the abundance of land that can be brought under crops and consequently the initially much higher returns to labor (see Annex 1).

We now turn to examine other inputs that increase the productivity of labor, such as fertilizer and seed.

In countries that have pursued a deliberate policy of smallholder intensification, such as Kenya, the use of purchased inputs like fertilizer and seed is much more common and corresponds to areas of high potential and high density (see Figure 28). According to the 1978 survey, farmers in the Central province of Kenya applied four times more fertilizer per hectare than did those in its closest competitor, the Eastern province—116 as compared to 27 kilograms per hectare. The Central province also accounted for over half of all sprays, seeds, feeds, and hired labor used in the smallholder sector for that year (see Annex 4). Because world prices for coffee and tea were reflected in producer prices, the production of higher value crops and the more intensive use of land naturally gravitated to the

Central province. As a result, incomes there were the highest in Kenya outside Nairobi, but distribution was the worst, confirming the Kuznetzian view that income inequalities may initially worsen with growth before they improve.

In Cameroon, another case presents itself: Input use is concentrated *both* in the higher density Western Highlands *and* in targeted cotton-producing regions in the North. Table 17 indicates that the ratio of farms using fertilizer and purchased seed in the highlands reached 74 and 64 percent, respectively—about 20 percentage points above the national average. Surprisingly, in the lower density Northern region (with 17 persons/per square kilometer), the ratio of farms using fertilizer was not much less: 61 percent. It would be useful to have data on levels of fertilizer application by regions and family size to carry out more detailed work, but such farm surveys are limited in Africa. Those familiar with Cameroon attribute greater fertilizer use in the North to the success of state-sponsored SODE-COTON projects in the region, reinforcing the argument for policy-led intensification.

Similarly, many attribute high rates of input use in the Southern region of Tanzania to explicit public policy objectives. Less than 10 percent of all fertilizer was applied in the high potential Northeast Highlands, but the Iringa region of the Southern Highlands (with a relatively low density of 20 persons per square kilometer) accounted for 22 percent of all fertilizer and 13 percent of the seed in 1980; by no small coincidence it also had five of the twelve state-financed national retail outlets serving farmers in 1980 (see Table 18). This suggests room for increasing yields and adds weight to the idea that input use follows regional planning more closely than it does population density.

Fertilizer use in Nigeria is directly related to state policy. Since 1977, the subsidy on fertilizer has been on average about 25 percent of the total agricultural budget. Nearly two-thirds of the total 580,000 metric tons of product

consumed in 1984 went to the Northern states (see Figure 29). Food crops account for 80 percent of all fertilizer use (Lele, Christiansen, Kadiresan 1989). The strong regional emphasis to fertilizer policy apparently does not complement regional potential; responses are reportedly higher in the low density Middle Belt states. Data on soils from FAO (see Annex 6) suggest that the majority of low productivity soils in Nigeria are located in the South.

In Malawi, land has become so scarce in the Southern region that small farmers can no longer produce enough food to feed their own families, let alone purchase inputs on the market. In the southern parts of Malawi, the ratio of households using inputs is significantly below the national average of 33 percent for fertilizer and 17 percent for purchased seed, at 23 and 8 percent, respectively (see Figure 30). The percentage of households purchasing seeds from ADMARC is also highest in the Central and to a lesser extent the Northern region (see Annex 5). Both the Northern and Southern regions of Malawi have a relatively lower population density than the Central region. In the North, the resultant greater land availability has contributed to the low level of intensification through increased use of inputs, whereas in the South the small farmers have lacked the financial means and the ability to undertake the risks associated with the purchase and utilization of fertilizer and hybrid seed. The degree of population pressure in the

Southern region, coupled with the failure to intensify agriculture there, has reached the point where it no longer acts as a positive inducement to intensify production but rather has begun a downward spiral of declining fertility, declining input use, and declining output. An unfortunate omission from the Boserup hypothesis is the effects of inadequate public policy. In Malawi, the problems arising from population pressure have as much to do with poor policy as they do with high population densities: The still inadequate access to sources of cash, credit (less than 20 percent of all small farmers receive credit), and purchased inputs have stifled the autonomous movement toward intensification.

Conclusion

Whether higher population densities are an important aid to development or a hindrance will remain an intensely complex and highly controversial issue. Boserup provides an intellectual justification for high population densities; a powerful body of opinion in Africa believes that higher population densities are necessary and desirable for future development. Fertility is highly valued culturally at the local level, and children are seen as assets in labor and insurance for old age; many social and cultural factors that resist empirical analysis will shape a country's movement toward more intensive, productive, and tenable use of land.

In this paper we have shown that:

1. Data on some of the most basic facts needed to plan agricultural development are scarce in Africa. They raise more questions than they answer.
2. Targeting policies and investments in the areas of high productive potential and high population densities offers the greatest scope for achieving growth in the short and medium run.
3. Achievement of this objective is complicated in Africa by the fact that there is less congruence between land potential and population densities due to factors such as disease, cultural barriers to migration, and colonial patterns of investments in infrastructure.
4. The political and welfare considerations of including the largest proportion of people in the growth process have influenced past patterns of public policy toward regional development. These considerations have been addressed differently in various countries. Only in Kenya and to a lesser extent in Cameroon did they achieve broad-based growth by using their regional comparative advantages. Elsewhere policies resulted in considerable redistribution in the sources of production and perhaps helped to commercialize agriculture. Countries will need to make difficult choices in the future to realize growth.
5. The policy-led process of intensification conceived here is different than the autonomous intensification envisaged by Boserup. Its implications are outlined in the Summary and Policy Recommendations section and will not be repeated here.

Arusha	Coffee A.	15%	Maize Wheat	29% 75%
Kilimanjaro	Coffee A.	36%		
COASTAL BELT				
Coast	Cashews	27%		
Lindi	Cashews	22%		
Mtwara	Cashews	42%	Cassava	51%
Tanga			Cattle	26%
Morogoro			Cattle	20%
CENTRAL AND WESTERN PLATEAU				
Dodoma			Maize Sorghum	13% 43%
Singida				
Tabora			Rice	25%
Kigoma				
SOUTHERN HIGHLANDS				
Mbeya	Coffee A.	21%	Rice Maize	53% 12%
Iringa				
Ruvuma	Coffee A.	15%	Maize	10%
Rukwa			Maize	11%
LAKE VICTORIA BASIN				
Mwanza	Cotton	38%	Cassava Cattle	21%
Mara				
Shinyanga	Cotton	38%	Rice	12%
Kagera	Coffee R.	99%		

Sources:

Maize data from NMC/MDB. Based on six-year (1976-1982) mean shares of NMC purchases.
Cassava data from NMC. Based on six-year (1976-1982) mean share of marketed production.
Wheat data from NMC/MDB. Based on six-year (1976-1982) mean share of marketed production.
Rice data from M.O.A./DSM (Price Policy Recommendations for 1981-82). Based on five-year (1975-1980) purchases of rice and paddy (converted at rate of 65%).
Sorghum Data from NMC. Based on six-year (1976-1982) mean share of marketed production.
Coffee data from TCMB. Shares represent TCMB purchases of Arabica and Robusta for 1985/86.
Cattle data from Statistical Abstract, 1973-1979. Total indigenous cattle holdings on large-scale farms (no. of cattle less significant for "Ujamaa" category.
Cotton data from TCMB (as cited in Agr. Sector Report 1987). Based on share of purchased seed cotton in 1984/85.
Cashew data from TCMB (as cited in FAO, op. cit). Based on six-year (1980-1986) mean share share of marketed production.

SOURCES: 1/ Statistical Abstract, Central Bureau of Statistics, Republic of Kenya. Years 1978, 1982, and 1985.
2/ IFS (IMF) 1985 Yearbook.

NOTE: Earnings or Wages cover all cash payments, including basic salary, cost of living allowances, profit bonus, together with the value of rations and free board, and an estimate of the employer's contribution toward housing. Earnings as shown in this section are lower than the estimate of factor income going to employees because they exclude pensions, employers contributions to the National Security Fund or private provident funds and personal emoluments for the armed forces. Earnings in the rural non-agriculture sector are excluded.

Sources: 1/ Malawi Population and Housing Census 1987: Preliminary Report. National Statistical Office: Zomba, 1988.

2/ Rural population projected from 1977 Census data (by district) to 1985 at 2.4949% p.a.. Rate of growth derived from Malawi Population Census, 1977: Analytical Report, Vol. II. p. 115, Table 9.1 which gives urban population at 8.5% in 1977 and roughly 25% in 2000. See also M POP file. Data not yet available from the 1987 Population Census.

3/ Malawi Population Census 1977: Vol. II (N.S.O./Zomba) p. 168, Table A.9.43.

4/ Land data from Malawi Population Census 1977, Analytical Report, Vol. 1., Table 2.4

5/ Cultivated land calculated from 1984/85 M.O.A. Crop Estimates for total customary hectarage, plus area under tobacco estates in 1985, by ADD, from Deloitte Haskins and Sell, 1986, "Proposed Extension and Training Service for the Estate Sub-Sector," reported in IBRD Malawi Land Policy Study, April 1987, p.21 Table 3.2

6/ Cultivable land figures from 1965, Department of Agriculture estimates, published in Compendium of Agricultural Statistics, 1977. (NSO: Zomba), Table 1. (Conv. to Ha. at 2.47) Arable land estimates are generally more conservative than the figures given above; the by Office of President has cited 19% in "SAL IV: A Proposal..." for arable land, and the World Bank has alternately cited 38% cultivabe (1981 Development of the Agricultural Sector Report) and more recently 22% without forests, 62% with (Land Policy Study 1987, p.7). Elsewhere Mkandawiri and Phiri, "Land Policy Study" (Jan. 1987) cite the figure of 37% arable as a national average. We use the figures above as they represent official government data and are more dissaggregated, to the district level, this despite that they may be overinflated.

7/ Fully gazetted forest reserves. Office of the President and Cabinet, "Statement of Development Policies 1987-1996." p.38 Table 5.1

8/ The use of Agricultural Development Divisions (ADD's) as sub-heads for districts is useful because much of the available data, ie National Sample Survey 1980/81 data, is only given by ADD. However, in some cases, such as Salima District, it appears that district boundries are not strictly observed.

* Computional errors in the line. Original (incorrect) numbers are used.

SOURCE: National Sample Survey of Agriculture 1980/81, Vol.II, Table 3.1

1/ The Central Region, as made up by the ADDs in it, is a little larger than the formal political Central Region because the Salima ADD includes part of the Mangochi District, which is part of the formal political Southern Region.
2/ Roots = Cassava + Potatoes + Other Roots.
3/ Millet and/or Sorghum hectarages.

NOTE: Percentages indicate percentage of total national crop hectarage under above crop.

Source: Population Data:
Nigeria, National Population Commission: "Problems and Prospects in Integrated Rural Development," 1980, Lagos.

Land Data:
P.E.T. Allen, "Land Use in Nigeria," 1981

Notes: 1/ Population growth projected at 2.5% for all states excepts Lagos, which was projected at 4.0%.
2/ Obtained by taking 75.3% of land area of each state (cited in "Impact of National Agricultural Research," Federal Ministry of Science and Technology, September 1985).
3/ Defined as having "limited capacity for storing nutrients and are subject to leaching."
4/ Ferralitic soils defined as "intensely leached and highly vulnerable to erosion." Hydromorphic soils are those that are waterlogged.

Table 2
Productivity potential of soils

FAO Soil Classes	Soil Types	Area		Location/States
High Productivity				
1.	—	—	—	—
Good Productivity				
2.	Hydormorphic/ Alluvial Soils	50,400	5.5%	Floodplains, Fadamas, Lake Chad
Medium Productivity				
3.	Ferruginous Soils	289,200	31.7%	Ogun, Oyo, Kwara, Bauchi and Borno; found less extensively in Sokoto; Kaduna, Niger, Benue, and Plateau.
Low Productivity				
4.	Vertisols; Lithosols; Regosols;	423,600	46.4%	Southwestern Nigeria; Benue, Plateau, Kwara, Borno, and Kano.
5.	Brown/Reddish Brown; Ferralitic Soils.	148,800	16.3%	Sokoto, Kano, Gongola; Ogun, Oyo, and Ondo.
TOTAL		912,000	100.0%

Notes

1. The six countries selected for analysis (Kenya, Malawi, and Tanzania in East Africa, and Cameroon, Nigeria, and Senegal in West Africa) collectively account for 40 percent of the population of Sub-Saharan Africa and 50 percent of its GNP. They cover almost all the ecological zones in Africa, ranging from the Sahelian and Guinea Savannah zones in the North to the equatorial rain forest in the South, and including the volcanic, humid, and semi-humid highlands of East and West Africa. Taken together, the six grow almost all the major crops of Africa, including tea, coffee, cocoa, tobacco, cotton, groundnuts, cashews, sisal, sugar, maize, sorghum, millet, and rice. They include two oil-exporting and four oil-importing countries, two land-surplus and four land-short countries. Despite their diverse physical characteristics, and although they have followed different policy paths and achieved different outcomes, the six countries have enough in common to permit fruitful comparison. MADIA is a REPAC-(Research Approval Committee) funded research project approved in June of 1984. The MADIA study has the active support of seven donor agencies from Denmark, France, the Federal Republic of Germany, Sweden, the United Kingdom, the United States, and the Commission of the European Communities.

2. Ruthenberg (1983, p.15) defines the R-value (or "intensity of rotation") as

$$R = \frac{Y_t \cdot 100}{Y_f + Y_t}$$

where: Y_t = years cultivated
Y_f = years fallow

Thus, if a plot were cultivated for 3 years continuously and then left fallow for the next 7 years, the R-value would equal 30. Similarly, annual cropping without fallow would have an R-value of 100, and growing more than one crop per year each year would have an R-value above 100.

3. The production of flue-cured tobacco is considered harmful to the environment insofar as the treatment process consumes a fair amount of wood and contributes to pressure on wood resources. However, the effects are occurring through the expansion of estates, bypassing smallholders from potential sales. For a more thorough critique of tobacco production on the environment, see Boehnert, 1988.

4. While recognizing the fundamental importance of irrigation, however, the MADIA study documents the extent to which the possibilities for small-scale irrigation, whether developed by farmers by using traditional means or the more modern tubewells and valley bottom development schemes, are unexploited *relative to the complex and capital-intensive large-scale irrigation.* Not only have governments shown frequent preference for such irrigation but donors have provided large support for it. Examples include the Bura irrigation scheme in Kenya (at the cost of $25,000 per hectare), the River Basin Development Authorities in Nigeria (at the cost of between $35,000 and $100,000 per hectare), the SAED irrigation schemes in the Fleuve (the cost of which is unknown but estimated by FAO at $50,000 per hectare), and the SEMRY projects in Northern Cameroon ($13,000 per hectare). Each exemplifies inappropriate technocratic approaches that donors supported because of historical political involvement without regard to the development of the appropriate capacity for their management. Important exceptions to this are the World Bank's support for tubewells and surface irrigation on Kebrija in Northern Nigeria and the valley bottom development in Cameroon.

5. Initially, Ruthenberg argues, land is at low productivity but in equilibrium. To increase the land's current productivity is to risk jeopardizing its future productivity. He observes, "the basic principle of farming is to change the natural system into one which produces more of the goods desired by man. The man-made system is an artificial construction which requires continuous economic inputs obtained from the environment to maintain its output level. Farming thus implies the abolition of an unproductive 'steady state' in favor of a man-created, more productive but unstable 'state,' and much of the farm input (tillage, fertilizers, weeding, etc.) is nothing but an effort to prevent the new state from declining towards an unproductive low-level steady state" (Ruthenberg 1980, p. 9). Increasing the intensity of cultivation increases the relative instability in the ecosystem. The danger of instability is that if sufficient inputs are not maintained (or invested) over time the plot will return not merely to its former low-productivity state, but to a state of lower potential, as is evidenced by "desertification" of marginal lands.

6. There are many cases where population growth, rather than increasing capital accumulation, has depressed savings and diverted investment away from production to consumption. See for instance Ruttan 1984.

7. For a more detailed discussion of the role of ethnicity on the making of agricultural policy, see Lele and Hanak, eds., *The Politics of Agricultural Policy*, forthcoming.

8. Note that in Nigeria a large work on land potential has been completed for the North-Central plains. See Ministry of Overseas Development 1979.

9. A good source of further reading on interactions between ecology and development economics can be found in H. Daly (1989).

10. Figure of 19 percent cited in "SAL IV: Adjustment with Growth and Development," Malawi Government (Office of the President/Ministry of Finance) Special Studies Document 1986/2 (January, 1987), p.vii.; figure of 56 percent arable is cited in *Malawi Population Census 1977: Analytical Report, Vol. I.* National Statistical Office (Zomba: 1984), p.3.

11. See for instance the "sources of growth" analysis in Jammeh and Lele 1988.

12. In Cameroon, regional demographic surveys were undertaken from 1960-65, but the first full national census was in 1976. Likewise in Senegal, the first complete national census in 1976 was predated only by an administrative census in 1960 and a demographic survey in 1961 (Domschke and Goyer 1986).

13. An intermediary step in the "normal" trajectory of intensification includes significant rural-to-urban migration as the productivity of labor decreases. Boserup writes that

> ...people in rural areas, instead of voluntarily accepting the harder toil of a more intensive agriculture, will seek to obtain more remunerative and less arduous work in non-agricultural occupations. (Boserup 1965, p. 118.)

14. We were fortunate to receive a significant contribution to this section from G.M. Higgins, who helped to draft the FAO/UNFPA/IIASA study. We are grateful for his reviewing this section and making helpful suggestions on the original manuscript.

15. Higgins, G.M./UNFPA/IIASA 1982. Three levels of input use are assumed in the FAO/IIASA analysis to calculate the kilocalorie production frontier:

a) *low level* assumes only land and labor, and no soil conservation;

b) *intermediate level* assumes improved hand tools and/or draft implements, some fertilizer and pesticide application, moderate soil conservation, and a cultivation mix of improved and traditional crops; and

c) *high level* assumes "complete mechanization, full use of genetic material," necessary farm chemicals, soil conservation measures, and cultivation of "only the most calorie (protein) productive crops on all potentially cultivable rainfed lands."

16. Several assumptions implicit in the FAO/IIASA analysis are masked by giving results in terms of sustainable populations. For every potential population that can be sustained (at given levels of input use), decisions have been made regarding optimal land use with respect to crops, consumer preferences, minimum calorie requirements, and response coefficients. These variables are used to calculate a production possibility frontier in kilocalories, based on agroclimatic and soil constraints. The assumptions remain largely hidden as the study lists only the end result: sustainable population figures.

17. In a recently published Ph.D. dissertation, Boehnert (1988) notes that "the increasing population is pressing more and more people into the arid and semi-arid areas. With them they bring their traditional farming practice, used in wetter and cooler areas with a different soil structure. For example, deep ploughing with heavy farm equipment and the custom of keeping the soil cultivated and open most of the year."

18. Crops can be high value in terms of relative price, but may not yield higher returns if yields are low. Cassava is considered a low value crop, but returns are higher than cocoa in Nigeria because of its high yields and the lower yields of aging cocoa trees that are nearing the end of the 20-year productive cycle.

19. One exception is the volcanic soils, found in highlands such as in Kenya and Western Cameroon, which are deep and remain highly productive year after year.

20. The importance of wood as a source of fuel is nicely illustrated by the fact that the cuisine of the Sahelian and Sudanian zones consists mainly of simmered stews, sauces, and grain porridges, whose preparation requires slow cooking and a great deal of wood using the traditional "three-stone" stove (Gorse and Steeds 1985, p. 29).

21. The critical position of Nigeria and Malawi is confirmed by other available evidence. The FAO Production Yearbook also has data on area under forest/woodlands that suggest a positive relationship between diminishing area under forests and woodlands and population densities. The area under forests decreased by 15 percent, for instance, in Nigeria during the 1974-84 period. In Malawi and Kenya, also characterized by high population pressures, forest area is listed as decreasing by 7 and 9 percent, respectively (see table A.3, annex). The figures are slightly less for Senegal (5 percent), Cameroon (4 percent), and Tanzania (2 percent).

22. A recent article in Kenya's *Weekly Review* presents the government position on the new Nyayo tea zones as "an outstanding example of President Daniel Arap Moi's commitment to environmental conservation. Inaugurated by the president himself in 1984, it was billed as one of the most effective means of protecting and conserving Kenya's forests against wanton destruction through illegal human settlements. Tea is planted in a thin strip of land adjacent to gazetted forests. The tea bushes provide ample soil cover curtailing soil erosion which normally sets in after trees are felled for saw milling and for other purposes. As trees are kept short by constant picking, it was expected that the tea zones would act as buffer zones and trespassers into forests are easily sighted from considerable distances" (*Weekly Review*, 1989).

23. It is now well established that symbiotic root microorganisms (*Rhizobium*, *Frankia*, and mycorrhizal fungi) can effectively contribute to tree productivity in marginal climatic and edaphic conditions. Since significant advances have been made recently in the manipulation of the microorganisms, it is not possible to contemplate their use in the field.... A number of trees have the potential for fixing atmospheric nitrogen through their symbiotic associations with *Rhizobium* (leguminous trees) or *Frankia* (nitrogen-fixing nonleguminous plants, now dubbed actinorrhizal plants). Promoting the nitrogen fixation capacity of these trees through inoculation with the proper symbiotic microorganisms or through selection of the plant host is an elegant approach to making the forest ecosystem self-sufficient in nitrogen (Gorse and Steeds 1985, p. 54).

24. See for instance *Forest Resources Crisis in the Third World*, Proceedings from the Conference, September 6-8, 1986. Sahabat Alam Malaysia (Penang: 1987). For a more optimistic scenario, see Anderson 1987.

25. Although in absolute terms the Rift Valley province contains more high potential land (911,500 hectares) than either the Central, Western, or Nyanza provinces, the relevant proportion of high potential to total land is much lower—only 6 percent as compared to about 25 percent in the Central province. The lower proportion of high potential land, the large tracts of medium and low potential land, and the inclusion of nomadic peoples in the equation—such as the Turkana and the Masai (who constitute just under 10 percent of the Rift Valley population)—may help explain the appearance of a more abundant supply of arable land in the Rift Valley whereas its high potential districts are equally densely populated.

26. The land survey was published in 1965, and subsequently republished in 1985 (Stobbs and Jeffers 1985). These figures are also cited by the government in 1977 *Compendium of Agricultural Statistics*. Arable land estimates are generally more conservative than the figures given above; the Office of the President, for example, has cited the figure of 19 percent arable in "SAL IV: A Proposal..." while the World Bank has alternately cited 38 percent cultivable ("1981 Development of the Agricultural Sector Report") and more recently 22 percent without forests, 62 percent with (Land Policy Study 1987, p.7). Elsewhere Mkandawiri and Phiri, "Land Policy Study" (1987) cite the figure of 37 percent arable as a national average. We use the first set of figures as they represent official government data and are more disaggregated (to the district level), although they may be high.

THE MADIA STUDY

Although many generalizations have been made about the agricultural crisis in Africa, relatively few detailed country and cross-country studies of African agriculture based on systematic data analysis have been conducted. Similarly, although foreign aid has constituted a large part of total government expenditures in Africa for close to fifteen years, there has been little analysis of the role of external assistance in African countries that goes beyond political criticism of official assistance or the alleged self-serving objectives of donors. The impetus for the study "Managing Agricultural Development in Africa" (MADIA) was to begin the process of filling this gap and to explain the nature and sources of the agricultural crisis, particularly the extent to which it originated in resource endowments, historical and contemporary events, external and internal policies, and the economic and political environment.

The MADIA study involved detailed analysis of six African countries—Kenya, Malawi, Tanzania, Cameroon, Nigeria, and Senegal. In addition to the World Bank, seven donors, USAID, UKODA, DANIDA, SIDA, the French and German governments, and the EEC participated in the study. The analysis of country policies and performance during the last 20-25 years was carried out with the benefit of substantial input from the governments and nationals of each of the countries represented. The study had three main areas of focus: (1) the relationship between domestic macroeconomic and agricultural policy and agricultural performance, (2) donors' role in the development of agriculture, and (3) the politics of agricultural policy.

The MADIA study was the result of encouragement and support from many people. Anne Krueger, former Vice President for Economic Research Staff in the World Bank, encouraged the establishment of these studies on aid and development in 1984. Gregory Ingram, former Director of the Development Research Department, provided unstinting support for the study. During the reorganization of the World Bank in 1986, the strong support from Benjamin King, then acting Vice President for Economic Research Staff, proved invaluable. Barber Conable, President of the World Bank, and Mr. Edward V. K. Jaycox, Vice President for the Africa Region, have played a key role by ensuring support for the study's completion, as did Stanley Fischer, the Vice President for Development Economics. Yves Rovani, Director General of the Operations Evaluation Department, was particularly helpful as the MADIA study drew heavily on the works of OED.

A special debt of gratitude is owed to the World Bank's Research Committee, which provided the initial funding for the study, and to the MADIA Steering Committee. In particular the strong support of the chair of the Steering Committee, Stephen O'Brien, has been of critical importance.

Finally, without the active and continued encouragement of many African policymakers and donor officials, including numerous colleagues in the World Bank, this study would not have provided new perspectives. This support has taken the form of numerous reactions to written and oral presentations, and refinement of the analysis to identify the areas of consensus and continuing controversy.
